BMJ Clinical Review Series

BPP School of Health is collaborating with BMJ to publish a series of major new reference titles across a number of subject areas. Each volume presents a range of important reference material on specific clinical topics. The content of each volume has been carefully selected from the wealth of information contained in the extensive recent archives of The BMJ and published in the various editions of the journal. These books will provide an invaluable reference source on current best practice for all clinicians.

Emergency Medicine, Perioperative and Critical Care

This book discusses a diverse range of traumas which can be presented in emergency medicine and the appropriate treatments to manage them. Topics discussed include:

- Emergency and early management of burns and scalds
- Management of the effects of exposure to tear gas
- Pain management and sedation for children in the emergency department
- The role of interventional radiology in traumas
- Management of paracetamol poisoning
- Pre-hospital management of severe traumatic brain injury
- Cardiopulmonary resuscitation
- Managing anaemia in critically ill adults
- Viral meningitis
- Diagnosis and management of pulmonary embolism

The BMJ Clinical Review Series along with companion volumes in other ranges which are under development on Research Methods, Ten Minute Consultations and Easily Missed Diagnoses, provides a succinct, accurate, up-to-date and easy accessible library of information on a broad series of medical issues which are relevant to clinicians at all levels in the medical profession. For further information on these series and the other titles we publish, please go to our web site; www.bpp.com/medical-series
About the publisher

BPP Learning Media is dedicated to supporting aspiring professionals with top quality learning material. BPP Learning Media’s commitment to success is shown by our record of quality, innovation and market leadership in paper-based and e-learning materials. BPP Learning Media’s study materials are written by professionally-qualified specialists who know from personal experience the importance of top quality materials for success.

About The BMJ

The BMJ (formerly the British Medical Journal) in print has a long history and has been published without interruption since 1840. The BMJ’s vision is to be the world’s most influential and widely read medical journal. Our mission is to lead the debate on health and to engage, inform, and stimulate doctors, researchers, and other health professionals in ways that will improve outcomes for patients. We aim to help doctors to make better decisions. BMJ, the company, advances healthcare worldwide by sharing knowledge and expertise to improve experiences, outcomes and value.

About the editors

Dr Babita Jyoti is a Radiation Oncologist with a special interest in Paediatric Proton Therapy. She graduated in Medicine in India followed by training in UK and obtained MRCP (UK) & FRCR (UK). She trained as a Clinical Oncologist at Clatterbridge Cancer Centre. She is currently working at the University of Florida Health Proton Therapy Institute in Paediatric Proton Therapy. She has been a PBL tutor and an OSCE examiner at Manchester Medical School.

Dr Michail A. Karvelis is a Pain Fellow at the Royal Liverpool and Broadgreen University Hospitals. He qualified from the Medical School of the Aristotle University of Thessaloniki, Greece in 2003. He trained as an anaesthetist both in Greece and the UK and he obtained his CCT in 2011. He was awarded a Masters degree in Pain management from Leicester University in 2011. He has worked as a consultant anaesthetist in the Naval Hospital of Athens and since 2014 he has been developing his special interest in regional anaesthesia and pain medicine in the NHS.
Introduction to Emergency Medicine, Perioperative and Critical Care

Physicians involved in emergency medicine, perioperative and critical care are confronted with challenging medical decision making every day; and each decision taken can be crucial for the patient. Keeping abreast of the evolutions in the field therefore is vital.

New developments are made constantly; with regular publication of results from clinical studies on topics such as cardiopulmonary resuscitation, diagnosis and treatment of life-threatening arrhythmias, initial resuscitation of trauma patients, mechanical ventilation, as well as perioperative fluid administration and pain management.

BMJ Clinical reviews represents an effort to contribute to delivering high-quality care to patients in the National Health Service and worldwide. In this book, we have carefully selected clinical reviews on emergency medicine, perioperative and critical care from The BMJ’s rich database, in an effort to help refresh and update knowledge on topics relevant to direct patient care.

We encourage healthcare professionals to use this book, taking advantage of the simple format to consolidate understanding, use the references to further knowledge, and continue to practice evidence based medicine.
Anaphylaxis: the acute episode and beyond

F Estelle R Simons, professor, department of paediatrics and child health, professor, department of immunology, Aziz Sheikh, professor of primary care research and development

Anaphylaxis is an alarming medical emergency, not only for the patient or caregiver, but also sometimes for the healthcare professionals involved. Although it is thought of as uncommon, the lifetime prevalence is estimated at 0.05-2%, and the rate of occurrence is increasing. Hospital admissions, although uncommon, are also increasing, as are admissions to critical care units. Many anaphylaxis episodes now occur in community settings. Accurate community based population estimates are difficult to obtain because of underdiagnosis, under-reporting, and miscoding, as well as use of different anaphylaxis definitions and different methods of case ascertainment in the populations studied. Although death from anaphylaxis seems to be uncommon, it is under-reported.

In this article, we draw on evidence from randomised controlled trials, quasi-experimental and other observational studies, and systematic reviews. We also reference key evidence based international and national anaphylaxis guidelines and their updates. How is anaphylaxis defined?

The widely used definition of anaphylaxis—a serious allergic reaction that is rapid in onset and may cause death—is accompanied by clinical criteria for diagnosis, which have been validated for use in clinical and research contexts (fig 1). In emergency departments, this definition has high sensitivity (97%) and high negative predictive value (98%), with lower specificity (82%) and positive predictive value (67%), as anticipated in a multisystem disease. Hypotension and shock are not prerequisites for making the diagnosis of anaphylaxis. Death occurs as often after respiratory arrest as it does after shock or cardiac arrest.

What are the mechanisms, triggers, and patient risk factors for anaphylaxis?

The clinical features of anaphylaxis result from sudden release of histamine, tryptase, leucotrienes, prostaglandins, platelet activating factor, and many other inflammatory mediators into the systemic circulation. Typically, this occurs through an immune mechanism involving interaction between an allergen and allergen specific IgE bound to high affinity IgE receptors on mast cells and basophils. However, IgE independent immune mechanisms and direct degranulation of mast cells are sometimes responsible, and other episodes, especially in adults, are idiopathic.

Patient risk factors for anaphylaxis include vulnerability owing to age or physiological state (box 2). Some diseases such as asthma and cardiovascular disease, and some drugs such as β adrenergic blockers and angiotensin converting enzyme inhibitors also increase the risk of severe or fatal anaphylaxis episodes (box 2). Cofactors that can amplify or augment acute anaphylaxis episodes have been identified (box 2). Doctors and patients should be aware of the relevant risk factors and cofactors in the context of long term management.

How do patients present with anaphylaxis?

Patients with anaphylaxis present with different scenarios. Some develop iatrogenic anaphylaxis after administration of a diagnostic or therapeutic agent. Others present to the emergency department after experiencing anaphylaxis in the community; in such patients, the duration of symptoms and signs varies from minutes to hours, and treatment with adrenaline (epinephrine), oxygen, intravenous fluids, an H1 antihistamine, a glucocorticoid, or other drug might have already been started. In addition, many patients present to their doctor with a history of anaphylaxis that occurred weeks, months, or even years earlier, which may or may not have been appropriately investigated or followed up. Regardless of the scenario, the clinical diagnosis of anaphylaxis is based on the history of the acute episode.

How is an acute episode of anaphylaxis diagnosed?

Clinical presentation

Anaphylaxis is characterised by symptom onset within minutes to a few hours after exposure to a food, drug, insect sting, or other trigger (box 1). Target organ involvement varies. Two or more body organ systems (cutaneous, respiratory, gastrointestinal, cardiovascular, or central nervous system) are usually affected (box 3; fig 1). To some extent, symptoms and signs depend on age and physiological state. As examples, infants and young children who cannot describe their symptoms typically develop sudden behavioural changes and become anxious, frightened, or clingy. Children sometimes use terms such as “burning” or “tingly” to mean itching, and those with upper airway involvement sometimes scratch at their throat or gag. Pregnant women can experience intense itching of the genitalia, abdominal cramps, back pain, signs of fetal distress, and preterm labour.

SOURCES AND SELECTION CRITERIA

We based this review on Medline and other searches for publications relevant to human anaphylaxis, including Cochrane reviews and other systematic reviews, randomised controlled trials, and quasi-experimental and other observational studies. We also used World Allergy Organization guidelines for the assessment and management of anaphylaxis and UK Resuscitation Council guidelines for emergency treatment of anaphylactic reactions (both of which were not commercially sponsored).

SUMMARY POINTS

- Diagnosis is based on clinical presentation—sudden onset of characteristic symptoms in more than one body system, minutes to hours after exposure to a likely or known allergen
- Factors associated with increased risk of severe or fatal anaphylaxis include asthma, cardiovascular disease, mastocytosis, and drugs such as β blockers
- When anaphylaxis occurs, promptly call for help, inject adrenaline intramuscularly, and place the patient on the back or in a semi-reclining position with lower extremities raised
- During the episode, if needed, give high flow supplemental oxygen, establish intravenous access to provide high volume fluids, and perform cardiopulmonary resuscitation
- Provide at risk patients with adrenaline autoinjectors, personalised anaphylaxis emergency action plans, and medical identification
- Confirm the specific trigger so that it can be avoided or allergen specific immune modulation—such as venom immunotherapy to prevent anaphylaxis from insect stings—can be carried out
Skin symptoms and signs are reported in 80-90% of patients. In their absence, anaphylaxis can be difficult to recognise. Upper and lower respiratory tract symptoms and signs occur in up to 70% of those experiencing anaphylaxis and cardiovascular symptoms and signs in about 45%. Gastrointestinal symptoms occur in about 45% and central nervous system symptoms and signs in about 15%.

The patterns of target organ involvement vary between patients, and in the same patient from one episode to another (fig 1). Symptoms and signs therefore differ from one patient to another and from one episode to another in the same patient in terms of type, number of organ systems affected, time of onset in relation to exposure to the inciting agent, and duration.

Anaphylaxis can range in severity from transient and unrecognised or undiagnosed episodes, to respiratory arrest, shock, cardiac arrest, and death within minutes. At the onset of an episode, it can be difficult or

Anaphylaxis is highly likely when any one of the following three criteria is fulfilled:

1. Sudden onset of an illness (minutes to several hours), with involvement of skin, mucosal tissue, or both (for example, generalised hives, itch, or flush or swollen lips, tongue, or uvula)

And at least one of the following:

- Sudden respiratory symptoms and signs (for example, shortness of breath, wheeze, cough, stridor, hypoxaemia)
- Sudden skin or mucosal symptoms and signs (for example, generalised hives, itch, or flush or swollen lips, tongue, or uvula)
- Sudden reduced blood pressure or symptoms of end organ dysfunction (for example, hypotonia (collapse), incontinence)

Or

2. Two or more of the following that occur suddenly after exposure to a likely allergen or other trigger* for that patient (minutes to several hours):

- Sudden skin or mucosal symptoms and signs (for example, generalised hives, itch, or flush or swollen lips, tongue, or uvula)
- Sudden respiratory symptoms and signs (for example, shortness of breath, wheeze, cough, stridor, hypoxaemia)
- Sudden gastrointestinal symptoms (for example, crampy abdominal pain, vomiting)

Or

3. Reduced blood pressure after exposure to a known allergen† for that patient (minutes to several hours):

- Infants and children: low systolic blood pressure (age specific) or greater than 30% decrease in systolic blood pressure‡
- Adults: systolic blood pressure of less than 90 mm Hg or greater than 30% decrease from that person’s baseline

---

* For example, immunological but IgE independent, or non-immunological (direct mast cell activation)

† For example, after an insect sting, reduced blood pressure might be the only manifestation of anaphylaxis; or, after allergen immunotherapy, generalised hives might be the only initial manifestation of anaphylaxis

‡ Low systolic blood pressure for children is defined as less than 70 mm Hg from 1 month to 1 year, less than (70 mm Hg + (2 x age)) from 1 to 10 years, and less than 90 mm Hg from 11 to 17 years. Normal heart rate ranges from 80 to 140 beats/min at age 1-2 years; from 80 to 120 beats/min at age 3 years; and from 70 to 115 beats/min after age 3 years. In infants and children, respiratory compromise is more likely than hypotension or shock, and shock is more likely to be manifest initially by tachycardia than by hypotension.

---

Fig 1 Clinical criteria for the diagnosis of anaphylaxis as illustrated in the 2011 World Allergy Organization anaphylaxis guidelines. These diagnostic criteria were developed by a National Institutes of Health sponsored international consensus group in 2004-06 to facilitate prompt recognition of anaphylaxis.”
impossible to predict the rate of progression, the ultimate severity, or the likelihood of death.\textsuperscript{1-14} In a UK registry study of anaphylaxis related deaths, median times to cardiac or respiratory arrest were five minutes in iatrogenic anaphylaxis, 15 minutes in insect sting anaphylaxis, and 30 minutes in food anaphylaxis.\textsuperscript{15}

Some patients develop biphasic or multiphasic anaphylaxis, in which symptoms resolve, then reappear hours later despite no further exposure to the trigger.\textsuperscript{16} Protracted anaphylaxis, in which uninterrupted symptoms recur for days despite treatment, is uncommon.\textsuperscript{17}

More than 40 differential diagnoses exist, including episodes of acute asthma, acute generalised urticaria, or acute angio-oedema, acute anxiety or panic attacks, and syncope (box 4).\textsuperscript{1, 2, 8-12, 15, 18}

What investigations should be considered?
Measurement of mast cell tryptase concentration—the most widely used laboratory test—is not universally available, takes hours to perform, is not available on an emergency basis, and is not helpful for confirming the clinical diagnosis of anaphylaxis in the initial minutes or hours after symptom onset. Treatment must therefore not be delayed to obtain a blood sample for tryptase measurement.

Total tryptase concentrations measured in serum during an anaphylaxis episode can, however, sometimes be helpful later to confirm the diagnosis, especially in patients with drug or insect sting induced anaphylaxis and those with hypotension.\textsuperscript{1, 2, 8-12, 15, 18} Tryptase concentrations are seldom raised in patients with anaphylaxis triggered by food, or in those whose blood pressure remains normal during the anaphylactic episode. Several factors may explain this: localised mast cell degranulation—for example, in the upper airway—with less tryptase entering the circulation than after generalised degranulation; involvement of respiratory epithelial mast cells rather than perivascular and cardiac mast cells that contain more tryptase; greater distance of respiratory epithelial mast cells than perivascular mast cells from the circulation; and involvement of basophils, which release minimal tryptase.\textsuperscript{26} A serum tryptase concentration within the reference range of 1-11.4 ng/mL does not refute the clinical diagnosis of anaphylaxis, and an increased concentration is not specific for anaphylaxis.\textsuperscript{19}

Tryptase has a short elimination half life. Serial measurements are reported to improve test specificity and are ideally obtained 15-180 minutes after symptom onset, one to two hours later, and after resolution of the episode. A raised baseline value suggests the diagnosis of mastocytosis rather than anaphylaxis.\textsuperscript{17, 18}

How should an acute episode of anaphylaxis initially be treated?
Figure 2 outlines a systematic approach to the basic initial management of anaphylaxis that emphasises the primary role of adrenaline.\textsuperscript{19} In healthcare settings, it is important to prepare for this medical emergency by using an anaphylaxis assessment and management protocol based on current national or international guidelines.\textsuperscript{1, 2, 28} This protocol should be displayed in locations where all healthcare professionals and staff can access it and rehearse it.

### BOX 2 PATIENT RISK FACTORS FOR ANAPHYLAXIS

#### Age related factors
- Infants: anaphylaxis can be hard to recognise, especially if the first episode; patients cannot describe symptoms
- Adolescents and young adults: increased risk taking behaviours such as failure to avoid known triggers and to carry an adrenaline autoinjector consistently
- Pregnancy: risk of iatrogenic anaphylaxis—for example, from β-lactam antibiotics to prevent neonatal group B streptococcal infection, agents used perioperatively during caesarean sections, and natural rubber latex
- Older people: increased risk of death because of concomitant disease and drugs

#### Concomitant diseases
- Asthma and other chronic respiratory diseases
- Cardiovascular diseases
- Mastocytosis
- Allergic rhinitis and eczema*  
- Depression, cognitive dysfunction, substance misuse

#### Drugs
- β adrenergic blockers†
- Angiotensin converting enzyme (ACE) inhibitors†
- Sedatives, antidepressants, narcotics, recreational drugs, and alcohol may decrease the patient’s ability to recognise triggers and symptoms

#### Cofactors that amplify anaphylaxis
- Exercise: anaphylaxis associated with exercise may be food dependent or food independent; non-steroidal anti-inflammatory drugs and other listed cofactors may also be relevant
- Acute infection such as an upper respiratory tract infection
- Fever
- Emotional stress
- Disruption of routine—for example, travel and jet lag
- Premenstrual status in women and girls

*Examples of mechanisms and triggers are given; the number of triggers is infinite.
†Different classes of drugs induce anaphylaxis through different mechanisms.
\textsuperscript{1}Consider the possibility of an uncommon or novel trigger (such as galactose α-1-3-galactose, the carbohydrate moiety in red meat; saliva infected by biting insects; or topically applied allergens such as chlorhexidine) or a concurrent diagnosis of mastocytosis.

### BOX 1 MECHANISMS AND TRIGGERS OF ANAPHYLAXIS

#### Immune mechanism: IgE dependent*
- Foods: peanut, tree nuts (such as cashews), milk, eggs, shellfish, finned fish, wheat, soy, sesame, kiwi
- Drugs*: penicillins and other β lactam antibiotics
- Biologicals: monoclonal antibodies, vaccines (rare)
- Insect stings: bees, hornets, wasps, yellow jackets, some ants
- Natural rubber latex
- Seminal fluid (rare)

#### Other immune mechanisms: IgE independent*
- IgG mediated: infliximab, high molecular weight dextran (rare)
- Immune aggregates: intravenous immunoglobulin (rare)
- Drugs*: aspirin, ibuprofen, and other non-steroidal anti-inflammatory drugs
- Complement and coagulation pathways

#### Direct mast cell and basophil activation*
- Exercise, usually with a cofactor such as a food or drug
- Other physical factors: for example, cold air or cold water
- Drugs*: opioids such as codeine or morphine

#### Idiopathic anaphylaxis**
- No trigger can be identified

\textsuperscript{1}Examples of mechanisms and triggers are given; the number of triggers is infinite.
\textsuperscript{2}Different classes of drugs induce anaphylaxis through different mechanisms.
At the time of diagnosis, exposure to the trigger should be halted if possible—for example, by discontinuing an intravenously administered diagnostic or therapeutic agent. The patient’s circulation, airway, breathing, mental status, skin, and body weight (mass) should be assessed. Simultaneously and promptly, call for help—from emergency medical services in a community setting or a resuscitation team in a hospital or other healthcare setting. In an adult, inject adrenaline 0.3 mg (0.3 mL) by the intramuscular route in the mid-outer thigh, to a maximum of 0.5 mg (0.5 mL) of a 1 mg/mL (1:1000) solution; in a prepubertal child, inject adrenaline 0.15 mg (0.15 mL) to a maximum of 0.3 mg (0.3 mL). Adrenaline is classified as an essential drug by the World Health Organization and

**Initial treatment of anaphylaxis**

1. Have a written emergency protocol for recognition and treatment of anaphylaxis and rehearse it regularly

2. Remove exposure to the trigger if possible—for example, discontinue an intravenous diagnostic or therapeutic agent that seems to be triggering symptoms

3. Assess patient’s circulation, airway, breathing, mental status, skin, and body weight (mass)

   **Promptly and simultaneously perform steps 4, 5, and 6**

4. Call for help: resuscitation team (hospital) or emergency medical services (community) if available

5. Inject adrenaline (epinephrine) intramuscularly in mid-outer thigh, 0.01 mg/kg of a 1:1000 (1 mg/mL) solution, to a maximum of 0.5 mg (adult) or 0.3 mg (child); record time of dose and repeat it in 5-15 minutes, if needed. Most patients respond to 1 or 2 doses

   Place patient on back or in a position of comfort if there is respiratory distress and/or vomiting; elevate lower extremities; deaths can occur within seconds if patient stands or sits suddenly

6. When indicated, give high flow supplemental oxygen by face mask

7. Establish intravenous access using needles or catheters with wide bore cannulas (14-16 gauge). When indicated, give 1-2 L of 0.9% (isotonic) saline rapidly (for example, 5-10 mL/kg in first 5-10 minutes to an adult; 10 mL/kg to a child)

8. When indicated, at any time, perform cardiopulmonary resuscitation with continuous chest compressions and rescue breathing

   In addition,

   Monitor (continuously, if possible) patient’s blood pressure, cardiac rate and function, respiratory status, and oxygenation

---

**Fig 2** Initial treatment of anaphylaxis as illustrated in the 2011 World Allergy Organization anaphylaxis guidelines.
is available worldwide in a 1 mL ampoule (1 mg/mL), even in low resource areas.\(^5\)

As soon as the symptoms of anaphylaxis are recognised, the injection should be given by anyone trained or authorised to administer it. In healthcare settings, it is typically ordered or given by a doctor. However, in many immunisation clinics, infusion clinics, and allergen immunotherapy clinics, nurses are preauthorised to do this.\(^6\) In community settings, adrenaline is often self injected through an autoinjector by the patient or injected by the parent, teacher, or other person responsible for the child. Delay in administration is associated with greater likelihood of biphasic and protracted anaphylaxis, and of death.\(^7\)\(^8\); in a UK series, only 14% of the patients who died from anaphylaxis received adrenaline before respiratory or cardiac arrest.\(^9\)

The adrenaline injection can be repeated after five to 15 minutes, if needed. When the initial injection is given promptly after symptoms are recognised, patients seldom require more than two or three injections. Compared with the intravenous route, the intramuscular route has the advantages of rapid initial access and a considerably wider margin of safety.\(^1\)\(^2\)

For ethical and practical reasons, no randomised controlled trials of adrenaline have been conducted during anaphylaxis. The recommendation for intramuscular injection of adrenaline is based on consistent clinical evidence supporting its use, observational studies, and objective measurements of adrenaline absorption in randomised controlled clinical pharmacology studies in people not experiencing anaphylaxis at the time of study.\(^11\)\(^12\)

The beneficial effects of adrenaline are time dependent.

** BOX 3 SYMPTOMS AND SIGNS OF ANAPHYLAXIS **

During an anaphylaxis episode, symptoms and signs can range from few to many. A comprehensive list is provided to aid in prompt recognition and to indicate the possibility of rapid progression to multiorgan system involvement.

**Skin, subcutaneous tissue, and mucosa**
- Nasal itching, congestion, rhinorrhea, sneezing
- Throat itching, tightness, dysphonia, hoarseness, dry staccato cough, stridor
- Lower airways: cough, increased respiratory rate, shortness of breath, chest tightness, wheezing
- Cyanosis
- Respiratory arrest

**Gastrointestinal**
- Abdominal pain, dysphagia, nausea, vomiting (stringy mucus), diarrhoea
- Constipation
- Vomiting
- Itching of the genitalia, palms, soles
- Itching or swelling (or both) of lips, tongue, palate, uvula, external auditory canals
- Itching of the oral mucosa

**Respiratory**
- Nasal itching, congestion, rhinorrhea, sneezing
- Throat itching, tightness, dysphonia, hoarseness, dry staccato cough, stridor
- Lower airways: cough, increased respiratory rate, shortness of breath, chest tightness, wheezing
- Cyanosis
- Respiratory arrest

**Cardiovascular**
- Chest pain (myocardial ischaemia)*
- Tachycardia, bradycardia (less common), other dysrhythmias, palpitations
- Hypotension, feeling faint, incontinence, shock
- Cardiac arrest

**Central nervous system**
- Feeling of impending doom, uneasiness, headache (pre-adrenaline), altered mental status or confusion owing to hypoxia, dizziness or tunnel vision owing to hypotension, loss of consciousness

**Other**
- Metallic taste in the mouth

*This can occur in patients with coronary artery disease and (owing to vasospasm) in those with normal coronary arteries.

** BOX 4 DIFFERENTIAL DIAGNOSIS OF ANAPHYLAXIS**

- Common diagnostic dilemmas*: acute asthma, acute generalised urticaria, acute angio-oedema*, syncpe or fainting, panic attack, acute anxiety attack
- Postprandial syndromes, such as food poisoning, scombroidosis, pollen-food allergy syndrome (oral allergy syndrome), monosodium glutamate reaction, sulphite reaction
- Flush syndromes, such as menopause, carcinoid syndrome
- Excess endogenous histamine syndromes, such as mastocytosis
- Upper airway obstruction as a result of non-allergic angio-oedema‡
- Shock (other forms), such as hypovolaemic, septic, or cardiogenic shock
- Non-organic diseases, such as vocal cord dysfunction, hyperventilation, psychosomatic episode, Munchhausen's stridor
- Other: certain tumours, system capillary leak syndrome (rare)

*The differential diagnosis is, to some extent, age dependent—for example, in infants, consider choking and foreign body aspiration, breath holding, and food protein induced enterocolitis. In middle aged or older patients, consider myocardial infarction or stroke.

\(^{\text{†}}\)Acute urticaria can occur with intermittent or subclinical infection.

\(^{\text{‡}}\)May be due to hereditary angio-oedema types I, II, and III; use of angiotensin converting enzyme inhibitors; or cancer. Non-allergic angio-oedema is typically not associated with itching or urticaria.

** BOX 5 DISCHARGE MANAGEMENT OF ANAPHYLAXIS AND LONG TERM RISK REDUCTION **

**Discharge management**
- Equip with an adrenaline autoinjector or a prescription for one*
- Give the patient an anaphylaxis emergency action plan (personalised, written)
- Provide medical identification (such as bracelet, wallet card)
- Arrange for a medical record electronic flag or chart sticker
- Make a follow-up appointment with a doctor (see below)

**Long term risk reduction: investigations for sensitisation to allergens**
- Skin tests or measurement of allergen specific IgE concentrations
- Challenge or provocation tests conducted by trained and experienced staff in a well equipped medical setting using incremental amounts of the relevant allergen, such as a food or drug

**Long term risk reduction: avoidance and immune modulation**
- Food triggered anaphylaxis: strict avoidance of relevant food(s)
- Drug triggered anaphylaxis: avoidance of relevant drugs and use of safe substitutes; if indicated, conduct desensitisation in a medical setting
- Stinging insect triggered anaphylaxis: avoidance of stinging insects; subcutaneous venom immunotherapy
- Idiopathic anaphylaxis: consider the possibility of a novel or atypical trigger; examine the skin and measure a baseline serum tryptase concentration to rule out mastocytosis
- Optimal management of asthma and other concomitant diseases*

*All doctors play an important role in preparing patients for self treatment of anaphylaxis by teaching them how to recognise the common symptoms and signs and how to inject adrenaline safely using an autoinjector. In addition, all doctors play a role in optimal management of asthma, cardiovascular disease, and other comorbidities that contribute to the severity of anaphylaxis and death.

†No adrenaline autoinjectors contain an ideal dose for infants weighing <10-12 kg.

‡Allergy and immunology specialists play an important role in ascertaining the trigger(s) of an anaphylaxis episode, providing written information about avoidance of specific triggers, and, where relevant, preventing anaphylaxis by desensitisation to a drug or initiating and monitoring stinging insect venom immunotherapy.

§See examples in box 1 footnotes.
When given promptly, it reduces the release of mast cell mediators and the possibility of escalation of symptoms. The transient anxiety, pallor, palpitations, and tremor experienced after administration of a relatively low first aid dose of exogenous adrenaline are caused by its intrinsic pharmacological effects. These symptoms are uncommon after an intramuscular injection of the correct adrenaline dose. They are similar to the symptoms caused by increased endogenous adrenaline during the “fight or flight” response to an acute stressful situation. Serious adverse effects such as hypertension or pulmonary oedema can occur after adrenaline overdose by any route of administration. They are most commonly reported after an intravenous bolus dose, overly rapid intravenous infusion, or intravenous infusion of a concentrated adrenaline solution (1 mg/mL (1:1000) instead of a solution that is appropriately diluted for intravenous use. Hypoxia, acidosis, and the direct effects of the inflammatory mediators released during anaphylaxis can contribute to cardiovascular complications.

Do not allow patients with anaphylaxis to stand or sit suddenly. They should be placed on their back (or in a semi-reclining position if dyspnoeic or vomiting) with their lower extremities elevated.

What additional treatment might be indicated for an acute episode of anaphylaxis?

At any time during the episode, when indicated, additional important steps include giving high flow supplemental oxygen and maintaining the airway, establishing intravenous access and administering high volumes of fluid, and initiating cardiopulmonary resuscitation with chest compressions before starting rescue breathing.

As soon as possible, start continuous monitoring of blood pressure, heart rate and function, respiratory rate, and oxygenation using pulse oximetry to titrate oxygen therapy (fig 2).

Do not delay prompt intramuscular injection of adrenaline—the first line drug—by taking time to draw up and give a second line drug such as an H1 antihistamine or a glucocorticoid. H1 antihistamines relieve skin and nasal symptoms and glucocorticoids might prevent biphasic or protracted symptoms, but these drugs fail to prevent release of the inflammatory mediators that escalate the response; fail to relieve life threatening upper or lower airway obstruction, hypotension, or shock; and fail to prevent death.

Promptly transfer patients who are refractory to initial treatment of anaphylaxis to the care of specialists in emergency medicine, critical care medicine, or anaesthesiology. Such specialists and their teams are trained, experienced, and equipped to provide skilled management of the airway and mechanical ventilation, and to manage shock by administering adrenaline or other vasopressors through an infusion pump. The absence of established dosing regimens for intravenous vasopressors necessitates frequent dose titrations based on continuous monitoring of vital signs, cardiac function, and oxygenation.

After treatment and resolution of anaphylaxis, keep patients under observation in a healthcare facility for at least four to six hours. Observe those who have experienced respiratory or circulatory compromise for eight to 10 hours, or even longer.

How should patients be equipped for self treatment of anaphylaxis in the community?

Tell patients that they have experienced a potentially life threatening medical emergency. If possible, they should be discharged with an adrenaline autoinjector, or at a minimum, a prescription for one, and taught why, when, and how to inject adrenaline (box 5). They should also be equipped with a personalised emergency action plan that lists common anaphylaxis symptoms to help them recognise a recurrence and reminds them to inject adrenaline promptly using an autoinjector and seek prompt medical help. Such plans typically also list patients’ confirmed anaphylaxis trigger(s), their relevant comorbidities (such as asthma or cardiovascular disease), and relevant concurrent drugs. In addition, patients should wear medical identification (bracelet or card) that states their diagnosis of anaphylaxis, its causes, and any relevant diseases or drugs.

Beyond the acute episode: how should anaphylaxis be investigated?

The natural course of anaphylaxis is one of recurrent acute episodes, unless the patient’s specific triggers are identified and consistently avoided. Appropriate investigation and follow-up after recovery from an episode may protect against recurrences. Confirm triggers suggested by a meticulous history of previous episodes by measuring allergen specific IgE in serum or by performing allergen skin tests (or both), because self-identification of food, drug, and stinging insect triggers by patients may be non-specific or incorrect and prevention of recurrence must be trigger specific. Avoid testing with large numbers of allergens because sensitisation to allergens is common even without a history of symptoms or signs after exposure to the specific allergen. Skin tests are optimally performed about four weeks after the acute episode, rather than immediately after, when test results may be falsely negative. Patients with a convincing history of anaphylaxis who have negative skin tests within a few weeks after an episode should be retested later.

Some patients will need additional investigations to rule out other diseases in the differential diagnosis. Patients with idiopathic anaphylaxis need additional tests to investigate any unusual or novel triggers and to rule out mastocytosis. Other patients might need additional tests to distinguish asymptomatic sensitisation to an allergen, such as a food or venom, from risk of subsequent clinical reaction to this allergen. Allergen component tests, such as microassay based immunoassays, might help to distinguish patients who are sensitised to an allergen and at increased risk of anaphylaxis after exposure to the allergen from those who are sensitised but clinically tolerant (remain asymptomatic after exposure to the allergen).

Most doctors will want their patients with anaphylaxis to be investigated by a qualified allergy specialist, although ready access to such specialists and to basic tests for sensitisation to allergens is a problem in many parts of the world. In the United Kingdom, an evidence and consensus based national care pathway has been designed to improve assessment and management of infants, children, and young people who have experienced anaphylaxis.
How can recurrences of acute anaphylaxis be prevented?

Personalised written instructions about avoidance of confirmed relevant trigger(s) and safe alternatives should be provided for patients at risk, who should also be directed to reliable, up to date information resources. In healthcare settings, flag medical records with “anaphylaxis” and list relevant triggers.² ³ ⁴ ¹⁴

For anaphylaxis to foods, strict avoidance of the relevant foods, even in trace amounts, is currently the only recommended approach for prevention of recurrence. Long term avoidance of food triggers can be stressful because of the threat of hidden crossreactive or cross contaminating allergens. New immune modulation strategies to achieve clinical and immunological tolerance to implicated foods and prevent recurrences of food triggered anaphylaxis are within reach, as demonstrated in randomised controlled trials, although they are not yet recommended for clinical implementation because of high adverse event rates.⁵ ² ³ ³³ ³⁴ ³⁵

For anaphylaxis to a drug, prevention of recurrence involves substitution of a safe effective non-crossreacting agent, preferably from a different pharmacological class. If such an agent is not available, desensitisation to the implicated agent is indicated to induce temporary clinical tolerance for one uninterrupted course of treatment with that agent. Desensitisation to antimicrobials, antifungals, antivirals, chemotherapeutics, monoclonal antibodies, and other agents is carried out in specialised hospital units.¹ ² ³ ⁴ ³⁵

For anaphylaxis to stinging insect venoms, recurrences can be prevented by a three to five year course of subcutaneous immunotherapy with the relevant standardised specific venom(s). This approach, which is based on high quality randomised controlled trials, should be initiated and monitored by an allergist. It leads to clinical and immunological tolerance, and in about 90% of adults and 98% of children, to long lasting protection against recurrence.¹ ³³ ³⁴ ³⁵

For exercise induced anaphylaxis and food dependent exercise induced anaphylaxis, recurrence can be prevented by avoiding relevant co-triggers such as foods, non-steroidal anti-inflammatory drugs, or alcohol and avoiding exercise under adverse environmental conditions (extreme cold or heat, high humidity, or high pollen counts). Patients should not exercise alone and should carry an adrenaline autoinjector and a mobile phone. If an episode occurs despite preventive measures, treatment involves discontinuing exertion immediately on recognition of initial symptoms, calling for help, and self injecting adrenaline promptly.¹

Pharmacological approaches are commonly used in the prevention of anaphylaxis. As an example, patients at high risk of anaphylaxis from infusion of radiocontrast medium during diagnostic procedures, or those with frequent episodes of idiopathic anaphylaxis, are often treated prophylactically with an H₁ antihistamine, glucocorticoid, or other drug. Most prophylactic regimens are based on clinical experience rather than on randomised controlled trials.¹

Do patients with a history of anaphylaxis need long term follow-up?

Patients at risk for anaphylaxis in the community should be monitored regularly—for example, at yearly intervals—by their doctor. Such visits provide the opportunity for personalised education on how to prevent recurrences, recognise anaphylaxis symptoms, and self inject adrenaline correctly. An important aspect of follow-up is to help patients (and carers of at risk children) control asthma or other comorbid disease that potentially increase the risk of severe or fatal anaphylaxis episodes.² ³ ³³ ³⁵

TIPS FOR NON-SPECIALISTS

- Be prepared to diagnose anaphylaxis on the basis of clinical criteria and to provide fast, effective, and safe treatment by injecting adrenaline 0.01 mg/kg (using a 1 mg/mL (1:1000) solution, to a maximum adult dose of 0.5 mg) intramuscularly in the mid-outer thigh
- Specialist referral is suggested for all patients to confirm specific triggers, discuss allergen avoidance, and if relevant, receive immunomodulation (for example, to prevent recurrence of anaphylaxis triggered by stinging insect venom) or investigate idiopathic anaphylaxis
- Specialist referral is strongly suggested for patients who are at increased risk of severe or fatal anaphylaxis because of concommitant asthma, cardiovascular disease, or mastocytosis

ADDITIONAL EDUCATIONAL RESOURCES

Resources for healthcare professionals
- World Allergy Organization (www.worldallergy.org)—Federation of 89 national and regional allergy and clinical immunology organisations; developed the World Allergy Organization Guidelines for the assessment and management of anaphylaxis
- Resuscitation Council UK (www.resus.org.uk)—Produced the Resuscitation Council (UK) guidelines for the emergency treatment of anaphylactic reactions

Resources for patients
- Anaphylaxis Campaign (www.anaphylaxis.org.uk)—This UK charity provides information, support, and a helpline for people with anaphylaxis
- Anaphylaxis Canada (www.anaphylaxis.ca)—This not for profit organisation supports, educates, and advocates for people with anaphylaxis and their families; it also supports anaphylaxis research
- Australasian Society of Clinical Immunology and Allergy (www.allergy.org.au)—ASCIA has developed anaphylaxis guidelines, action plans, a list of frequently asked questions about adrenaline autoinjectors, and e-training for first aid (community) treatment of anaphylactic reactions
- Food Allergy Research and Education (www.foodallergy.org)—This not for profit organisation (formerly the Food Allergy and Anaphylaxis Network) is dedicated to food allergy research and education, with the mission of ensuring the safety and inclusion of people with food allergies; while seeking a cure

AREAS OF ONGOING RESEARCH

- Development of rapid in vitro tests to confirm the clinical diagnosis at the time of the episode
- Development of additional in vitro tests to distinguish patients at risk of anaphylaxis from those with asymptomatic sensitisation
- Observational studies of adrenaline in anaphylaxis and randomised controlled clinical pharmacology studies (with or without placebo) of different doses and routes of administration in people not experiencing anaphylaxis at the time of study
- Randomised placebo controlled trials (listing clinical trial registration numbers) of second line drugs, such as systemic glucocorticoids, in patients with anaphylaxis
- Randomised controlled trial (clinical trial registration number ISRCTN29793562) of access to a 24 hour helpline providing expert management advice for the emergency management of anaphylaxis in infants, children, and young people
- Randomised placebo controlled trials of immune modulation to prevent anaphylaxis from food (listing clinical trial registration numbers)
The authors sincerely appreciate the help of Lori McNiven, and Jacqueline Schaffer, who prepared the figures. We thank the editors and reviewers for their constructive feedback.

Burn injuries are an important global health problem. Most simple burns can be managed by general practitioners in primary care, but complex burns and all major burns warrant a specialist and skilled multidisciplinary approach for a successful clinical outcome. This article discusses the principles behind managing major burns and scalds using an evidence-based approach and provides a framework for managing simple burns in the community.

What is the burden of burn injuries?

Annually in the United Kingdom, around 175,000 people attend accident and emergency departments with burns from various causes (box 1). This represents 1% of all emergency department attendances, and about 10% of these patients need inpatient management in a specialist unit. A further 250,000 patients are managed in the community by general practitioners and allied professionals. Of patients referred to hospital, some 16,000 are admitted, and about 1000 patients need active fluid resuscitation. The number of burns-related deaths averages 300 a year.

Globally, the World Health Organization estimates that 322,000 people die each year from fire-related burns. This could be an underestimate, however, because we have no valid comprehensive statistics from developing countries, where >95% of these deaths occur. High population density, illiteracy, poverty, and unsafe cooking methods contribute to the higher incidence in developing countries.

How is the area of a burn estimated?

In adults, Wallace’s “rule of nines” is useful for estimating the total body surface area—18% each for chest, back, and legs, 9% each for head and arms apiece, and 1% for the perineum. It is quick to apply and easily remembered, although it tends to overestimate the area by about 3%. The Lund and Browder chart takes into account changes in body surface area with age (and growth). It is useful across all age groups and has good interobserver agreement. Another useful, but rather subjective, guide is to use the surface area of the patient’s palm and fingers, which is just under 1% of the total body surface area. This method is useful for estimating small burns (<15%) or large burns (>85%). In large burns, the burnt area can be quickly calculated by estimating the area of uninjured skin and subtracting it from 100. A common mistake is to include erythema—only de-epithelialised areas should be included in these calculations.

How is the depth of a burn assessed?

Clinical estimation of burn depth (fig 1) is often subjective—an independent blinded comparison among experienced surgeons showed only 60-80% concurrence. Burn wounds are dynamic and need reassessment in the first 24-72 hours, because depth can increase after injury as a result of inadequate treatment or superadded infection. Burn wounds can be superficial in some parts but deeper in other areas (fig 2). The table shows some characteristic features of burns of varying depth.

A blinded rater comparison of laser Doppler imaging, which assesses skin blood flow, with clinical assessment and histopathology found that imaging was 90-100% sensitive and 92-96% specific for estimating burn depth. However, the high outlay costs for this equipment preclude its use outside specialist burns units. Other methods such as transcutaneous videomicroscopy (direct visualisation of dermal capillary integrity) and infrared thermography (temperature gradient between burnt and intact skin) remain largely experimental.

The terms “partial thickness” or “full thickness” burns describe the level of burn injury and indicate the likelihood and estimated duration for healing to occur. Superficial burns usually heal (by epithelialisation) within two weeks without surgery, whereas deeper burns probably need excision and closure of the area, often with skin grafts. Hypertrophic scarring is more common in deeper burns treated by surgery and skin grafting than in superficial burns.
What factors influence outcome?
Logistic regression analysis of survival data from 1665 burns patients from the Massachusetts General Hospital identified three risk factors for death: age over 60 years, more than 40% of body surface area injured, and inhalation injury.11 As survival outcomes have improved (mortality about 5-6% in resourced centres),11 however, assessment of outcome has shifted from mortality to quality of life measures.11 Thus, the current focus in burns patients is the preservation of function, reconstruction, and rehabilitation.11

How are minor burns managed?
Flowchart 1 (web fig 1 on bmj.com) provides a guideline for managing a “minor” burn in the community. The European working party of burns specialists recommends cleaning burns with soap and water (or a dilute water based disinfectant) to remove loose skin, including open blisters.13 Although the clinical evidence for “deroofing” of blisters is poor, without deroofing burn depth cannot be assessed. All blisters should therefore be deroofed, apart from isolated lax blisters <1 cm² in area, which can be left alone.14 A simple non-adhesive dressing, such as soft silicone (for example, Mepitel), padded by gauze is effective in most superficial and superficial dermal burns. However, biological dressings such as Biobrane are better, especially for children, because they reduce pain, and the wound bed can be inspected through the translucent sheet.15 New non-animal derived synthetic polymers such as Suprathel look promising for treating partial thickness burns, but further studies are needed. Silver sulfadiazine can be used for deep dermal burns. Dressings should be examined at 48 hours to reassess depth and the wound in general, and dressings on superficial partial thickness burns can be changed after three to five days in the absence of infection. If evidence of infection exists, daily wound inspection and dressing change is indicated. Deep dermal burns need daily dressings until the eschar has lifted and re-epithelialisation is under way, after which dressings can be changed more often.

When is referral to a specialist burns unit needed?
Box 2 shows the criteria for referring a “complex” burn to the specialist burns unit. Small area burns that take more than 14 days to heal; become infected; or are likely to worsen tissue ischaemia and local oedema (face, hands, feet, across flexures, genitalia) may also need to be referred.

How should major burns be managed?
All major burns should be managed initially according to trauma resuscitation guidelines.13 Box 3 shows a consensus summary on first aid management (prehospital care) for burns,18 and box 4 shows the principles for managing any large burns.

Prompt irrigation with running cool tap water for 20 minutes provides optimal intradermal cooling.18 Ice and very cold water should be avoided because they cause vasoconstriction and worsen tissue ischaemia and local oedema.19 Hypothermia should be avoided, especially in children. Patients with chemical burns may need longer periods of irrigation (up to 24 hours), and specific antidote information should be obtained from the regional or national toxicology unit.

The prehospital consensus guidelines emphasise that dressings help relieve pain from exposed nerve endings and keep the area clean.18 Polyvinylchloride film (such as clingfilm) is useful, but remember that circumferential wrapping can cause constriction. Cellophane films can worsen chemical burns, so the area should be irrigated thoroughly until pain has decreased and only wet dressings should be applied. Intravenous opiates or intranasal diamorphine should be used for analgesia.

All patients with facial burns or burns in an enclosed area should be assessed by an anaesthetist and the need for early intubation ascertained before transfer to a specialist unit. In full thickness circumferential burns—especially to the neck, chest, abdomen, or limbs—escharotomy may be needed to avert respiratory distress or vascular compromise of the limbs from constriction. Flowcharts 2 and 3 (web figs 2 and 3 on bmj.com) show the management of patients in the emergency department or the specialist burns unit.

What is the role of fluid resuscitation?
Effective fluid resuscitation remains the cornerstone of management in major burns. If more than 25% of the body is burnt, intravenous fluids should be given “on scene,” although transfer should not be delayed by more than two attempts at cannulation.18 The aims are to maintain vital organ perfusion and tissue perfusion to the zone of stasis (around the burn) to prevent extension of the thermal necrosis. In the UK, expert consensus recommends that

**BOX 1 SOME IMPORTANT CAUSES OF BURNS AND SCALDS**

- Flame burns
- Scalds (hot liquids)
- Contact burns (hot solid)
- Chemicals (acids or alkalis)
- Electrical burns (high and low voltage)
- Flash burns (burns resulting from brief exposure to intense radiation)
- Sunburns
- Friction burns
- Radiation burns
- Burns from lightning strike

**BOX 2 NATIONAL BURN INJURY GUIDELINES FOR REFERRAL TO A BURNS UNIT**

All complex injuries should be referred. Such injuries are likely to be associated with:

- Extremes of age (<5 or >60 years)
- Site of injury
- Face, hands, or perineum
- Any flexure including neck or axilla
- Circumferential dermal burns or full thickness burn of the limb, torso, or neck
- Inhalation injury (excluding pure carbon monoxide poisoning)
- Mechanism of injury
- Chemical burns >5% total body surface area (except for hydrofluoric acid when >1% area needs referral)
- Exposure to ionising radiation
- High pressure steam injury
- High tension electrical injury
- Hydrofluoric acid burns >1%
- Suspected non-accidental injury in a child (if delayed presentation, unusual pattern of injury, inconsistent history, discrepancy between history and clinical findings, multiple injuries, or old scars in unusual anatomical locations)
- Large size
- Child (<16 years old) >5% total body surface area
- Adult (≥16 years) >10% total body surface area
- Coexisting conditions
- Serious medical conditions (such as immunosuppression)
- Pregnancy
- Associated injuries (fractures, head injury, or crush injuries)
Characteristic features of burns of different depths

**How much fluid?**

Several formulae, based on body weight and area burnt, estimate volume requirements for the first 24 hours. Although none is ideal, the Parkland formula (3-4 ml/kg/% burn of crystalloid solution in the first 24 hours, with half given in the first eight hours) and its variations are the most commonly used. Resuscitation starts from the time of injury, and thus any delays in presentation or transfer to the hospital or specialist unit should be taken into account and fluid requirement calculated accordingly. Resuscitation formulae are only guidelines, and the volume must be adjusted against monitored physiological parameters.

**How should resuscitation be monitored?**

The use of urine output alone to assess adequate fluid resuscitation in burns has been challenged. Invasive haemodynamic monitoring with central venous pressure or pulmonary artery catheters are not recommended for routine monitoring of fluid replacement in burns because of the risk of infection. Less invasive monitoring using thermolisation methods to measure intrathoracic blood volume, cardiac output, and cardiac index have recently received attention. Although preliminary studies have suggested that this may aid resuscitation, one RCT failed to support these findings in burns.

**What is the role of nutrition?**

The role of nutritional support in major burns has shifted from one of preventing malnutrition to one of disease modulation. Nutritional requirements are dynamic, and early debridement and skin cover result in a 50-75% increase in energy expenditure. Thus, a nutritional plan—taking factors such as the extent and depth of the burn, the need for repeated surgical interventions, the appropriateness of the enteral or parenteral route, and the pre-injury health status of the patient—should be implemented within 12 hours.
Psychosocial aspects

The psychological requirements of patients and their carers change over the early resuscitative phase, acute phase, and rehabilitation phase. The prevalence of depression is estimated to be high (up to 60%) in burns inpatients, and up to 30% have some degree of post-traumatic stress disorder. All burns centres offer specialist advice on long-term psychosocial adjustment in burns patients. Changing faces in the UK and the Phoenix society in the United States provide excellent support for burns survivors.

How are scar and burn areas managed after healing?

A retrospective cohort study of 337 children with up to a five year follow-up found hypertrophic scarring in less than 20% of superficial scalds that healed within 21 days but in up to 90% of burns that took 30 days or more to heal. Appropriate treatment must therefore be instituted early and infection prevented to encourage rapid healing. Healed burns do not have adnexal structures, and are therefore dry, sensitive, and irregularly pigmented. Hence the area should be moisturised and massaged to reduce dryness and to keep the healed area supple. A sun cream, with a sun protection factor of 30, is advised to prevent further thermal damage and pigmentation changes.

New directions in burn wound management

Although autografting is the gold standard for skin replacement in burns, limited availability of donor skin precludes this option in large area burns. Hence, various tissue engineered skin substitutes (fig 3) have been developed to provide temporary or permanent wound coverage.

Processed skin from human cadavers—in which the cells are removed to leave a non-antigenic dermal scaffold—is used as a dermal replacement for treating deeper burns. Allogeneic fibroblasts, obtained from neonatal human foreskin and cultured in vitro, seeded on a biologically absorbable scaffold or on a nylon mesh, have also been developed. The proliferating fibroblasts secrete collagen, matrix proteins, and growth factors and aid healing. Composite skin substitutes comprising allogeneic keratinocytes (epidermal equivalent) and fibroblasts (dermal equivalent) are also available.

Although a recent meta-analysis of 20 RCTs has shown these substitutes to be safe, their efficacy could not be determined on the basis of current evidence.
Contributors: SE and AR designed the paper, carried out the literature search, collated the up to date evidence, and prepared the manuscript. SE created the flow charts and AR created fig 3. Both authors contributed equally in the development and completion of this article. MS is the senior author who proofread the article, provided invaluable suggestions, did the necessary corrections and amendments, and provided the expert advice. SE is guarantor.

Competing interests: None declared.

Provenance and peer review: Commissioned; externally peer reviewed.

Early fluid resuscitation in severe trauma

Tim Harris, professor of emergency medicine, G O Rhys Thomas, Lieutenant Colonel and honorary consultant, Karim Brohi, professor of trauma sciences and consultant trauma and vascular surgeon

Trama is a global health problem that affects patients in both rich and poor countries and accounts for 10 000 deaths each day. Trauma is the second leading cause of death after HIV/AIDS in the 5-45 year old age group. Early triage and resuscitation decisions affect outcome in trauma situations. The two leading causes of mortality in trauma are neurological injury and blood loss. There has been considerable improvement in our understanding of trauma resuscitation in the past 20 years, and data from databases and observational trials suggests outcomes are improving.

For patients with severe traumatic injuries (defined as >15 by the injury severity score, an anatomical scoring system), the high volume fluid resuscitation promoted by early advanced trauma life support manuals, followed by definitive surgical care, has given way to a damage control resuscitation (DCR) strategy.

This DCR approach has seen a fall in the volume of crystalloid delivered in the emergency department and an associated fall in mortality.

In this review, we summarise the evidence guiding the initial period of resuscitation from arrival in the emergency department to transfer to intensive care or operating theatre, focusing on trauma in critically injured adults. This article emphasises newer developments in trauma care. There is debate on whether patients with brain injury should be resuscitated to higher blood pressures, which is briefly discussed later in the text.

KEY COMPONENTS OF DCR

- Permissive hypovolaemia (hypotension) (see summary points)
- Haemostatic transfusion (resuscitation)—that is, fresh frozen plasma, platelets, or packed red blood cells, and tranexamic acid. Avoidance of crystalloids (normal saline, Hartmann’s, Ringer’s lactate solutions), colloids (a substance microscopically dispersed evenly throughout another substance; with resuscitation fluids, this term refers to larger molecules dispersed most usually in normal saline, such as gelofusion, haemaccel, or volulyte), and vasopressors
- Damage control surgery or angiography to treat the cause of bleeding
- Restore organ perfusion and oxygen delivery with definitive resuscitation

SUMMARY POINTS

- Critically injured trauma patients may have normal cardiovascular and respiratory parameters (pulse, blood pressure, respiratory rate), and no single physiological or metabolic factor accurately identifies all patients in this group.
- Initial resuscitation for severely injured patients is based on a strategy of permissive hypovolaemia (hypotension) (that is, fluid resuscitation delivered to increase blood pressure without reaching normotension, aiming for cerebration in the awake patient, or 70-80 mm Hg in penetrating trauma and 90 mm Hg in blunt trauma) and blood product based resuscitation
- This period of hypovolaemia (hypotension) should be kept to a minimum, with rapid transfer to the operating theatre for definitive care
- Crystalloid or colloid based resuscitation in severely injured patients is associated with worse outcome
- Once haemostasis has been achieved, resuscitation targeted to measures of cardiac output or oxygen delivery or use improves outcome
- Tranexamic acid administered intravenously within 3 h of injury improves mortality in patients who are thought to be bleeding

SOURCES AND SELECTION CRITERIA

We searched Medline, Embase, the Cochrane database, and Google for randomised controlled trials, meta-analyses, and peer reviewed articles, limiting the search to adults. The search was performed once by the lead author (TH) and once by a professional librarian. All articles were shared and supplemented by the author’s own libraries. The main search terms used were “trauma,” “resuscitation,” “fluid,” and “goal directed therapy.” Ongoing studies were identified from www.clinicaltrials.gov.

How can patients who need DCR be identified?

A DCR strategy applies to patients who present with suspected major haemorrhage. While many definitions exist, the most practical in the acute trauma setting is for estimated blood transfusion volumes of over four units in the initial 2-4 h. Identifying these patients can be a challenge because they are often young with good physiological reserve and may have no physiological evidence of hypovolaemic shock. A number of tools have been developed to identify this group of patients; however, physician decision and experience have been found to be just as accurate. Failure to identify these patients early and to apply DCR is associated with excess mortality.

How can trauma patients in shock be identified?

Shock may be defined as a life threatening condition characterised by inadequate delivery of oxygen to vital organs in relation to their metabolic requirements. A systolic blood pressure of 90 mm Hg is commonly used to define both hypotension and shock; however, oxygen delivery depends on cardiac output rather than blood pressure. Homeostasis with peripheral vasoconstriction acts to preserve blood pressure even as circulating volume is lost. In patients who have had trauma, adequate cardiac output cannot be inferred from blood pressure. Only when blood loss approaches half the circulating volume or occurs rapidly is there a relation between the cardiac output and blood pressure. Patients presenting with hypotension, tachycardia, and obvious blood loss are readily identified as being in a state of haemorrhagic shock. However, many patients will maintain their pulse and blood pressure even after massive blood loss and tissue hypoxia. This condition is termed cryptic shock and is associated with increased mortality.

The role of basic physiological parameters to estimate the severity of blood loss has been popularised in the advanced trauma life support courses and manuals. These materials describe physiological deterioration with increasing volumes of blood loss, and categorise four stages of shock. But data from a 1989-2007 analysis of the United Kingdom Trauma Audit Research Network database suggest that this model is not reflected in practice. Patients with progressive levels of blood loss to stage 4 haemorrhagic shock (equating to >2 L blood loss) were found to increase their pulse rates from 82 to 95 beats per minute, not to change respiratory
rates or Glasgow coma scale, and maintain systolic blood pressures above 120 mm Hg.7 Although an important part of the initial assessment, physiological derangement alone is neither sensitive nor specific as a tool to identify shock in trauma patients.7

There is observational evidence from large datasets in the UK and United States that mortality increases in trauma patients in both blunt and penetrating trauma, while systolic blood pressure falls below 110 mm Hg.10,11,12,13 A US review of 870 cases of trauma records identified that for every 10 mm Hg below 110 mm Hg, mortality increased by 4.8%.14 Shock index does not improve after risk stratification of trauma patients.15

Metabolic assessment with lactate16,17 and base excess18,19 also predicts blood loss and mortality. Furthermore, these parameters may be increased from exercise around the time of injury (running, fighting) or may be (falsely) low if the hypoxic tissues are not being perfused sufficiently to wash anaerobic products into the circulation (for example, when a tourniquet is applied). For patients in whom central access is obtained, mixed venous oxygen saturation is also a good indicator of blood loss, with levels below 70% suggesting inadequate oxygen delivery.20

Estimated injuries and associated blood loss are an important part of the initial trauma assessment. Clinical examination is augmented by focused ultrasound assessment of the chest, pericardium, and peritoneal cavity (extended focused assessment with sonography in trauma (eFAST), a specific but insensitive test for blood loss); and computed tomography (a sensitive and specific test for blood loss).

What is permissive hypotension (hypovolaemic) resuscitation?

Permissive (hypotension) hypovolaemic resuscitation is used to describe a process that minimises administration of fluid resuscitation until haemorrhage control has been achieved, or is deemed unnecessary on definitive imaging. Resuscitation is the restoration of oxygen delivery and organ perfusion to match requirements. In the 1960s and 1970s, a strategy of high volume crystalloid resuscitation in a ratio of 3 mL per 1 mL of blood loss was promoted, which was thought to replace intravascular and interstitial losses and reduce the risk of organ failure.16 However, vigorous fluid resuscitation increases blood pressure, the effect of which increases hydrostatic forces on newly formed clot, dilutes clotting factors and haemoglobin, and reduces body temperature. These effects could promote further bleeding. In permissive hypotension, definitive resuscitation is deferred until haemostasis is obtained. It is now recognised that aggressive crystalloid resuscitation also impairs organ perfusion.21,22

What evidence do we have for hypovolaemic resuscitation?

Considerable animal work has informed our understanding of hypovolaemic resuscitation. In summary, this research found that withholding fluid resuscitation from animals with critical blood loss (about half their circulating volume) was associated with death, whereas animals with less severe blood loss had a lower mortality with no fluid resuscitation.17

The table summarises three randomised controlled trials exploring the risks and benefits of hypovolaemic resuscitation.16,17,27 These trials provide evidence of a mortality advantage in favour of this resuscitation strategy for truncal penetrating trauma and evidence of no harm in blunt trauma.

The National Institute for Health and Clinical Excellence has recommended that in older children and adults with blunt trauma, no fluid be administered in the prehospital resuscitation phase if a radial pulse can be felt, or for penetrating trauma if a central pulse is palpable.18 In the absence of this, 250 mL crystalloid fluid boluses are administered and the patient is reassessed until these pulses, as described, return.

Much of the evidence for hypovolaemic resuscitation was developed before the advent of haemostatic resuscitation, as described below. This period of hypovolaemic resuscitation is maintained for as short a period as possible, until the injury complex is defined and any sites of blood loss treated surgically or embolised.

Untreated hypovolaemic shock leads to microvascular hypoperfusion and hypoxia, leading to multiorgan failure.19 Hypovolaemic resuscitation sacrifices perfusion for coagulation and haemorrhage control. The trauma team carefully balances the resuscitation process to maintain organ perfusion but at lower than normal blood pressure to regulate bleeding. Based on the evidence available, we suggest that fluid resuscitation before haemorrhage control should aim to maintain a systolic blood pressure of 80 mm Hg or a palpable radial pulse or cerebration by using small volume boluses of 250 mL. This value is arbitrary with little evidence to support it. The 250 mL boluses are able to increase blood pressure, since the circulation is highly constricted with a small volume of distribution. In practice, achieving target blood pressures is challenging. Patients

with severe injuries will probably need blood product based resuscitation, as described below.

**Fluid resuscitation in traumatic brain injury**

This review does not deal in detail with the complexities of resuscitation in brain injury; however, retrospective observational data for patients with traumatic brain injury suggest that any single reduction in mean arterial blood pressure below 90 mm Hg is associated with a doubling in mortality. Guidelines published by the Brain Trauma Foundation advocate maintaining a systolic blood pressure above 90 mm Hg but do not specifically state whether this is during active haemorrhage. Currently, there is controversy about whether the guidelines for permissive hypotension should be changed in the presence of head injury because there is no human evidence from prospective studies.

**What is the role of blood products in trauma resuscitation?**

Severe bleeding in trauma patients can result in disordered blood clotting. Until recently, this effect was thought to be a late phenomenon arising primarily from loss of coagulation factors during haemorrhage and dilution from resuscitation fluids. However, it is now recognised that trauma induced coagulopathy occurs within minutes of injury, and is associated with a fourfold increase in mortality. The process is multifactorial but is partly due to an endogenous coagulopathy that occurs as a result of tissue damage in severe shock. This understanding has led to changes in the management of trauma haemorrhage.

**Haemostatic resuscitation**

Haemostatic resuscitation is a combination of strategies targeting trauma induced coagulopathy to reduce bleeding and improve outcomes. How do blood products aid in resuscitation?

The main strategy to treat trauma induced coagulopathy is to provide volume replacement that augments coagulation. This replacement has been achieved by the transfusion of fresh frozen plasma, platelets, and packed red blood cells. A retrospective observational study performed on military personnel with similar injuries but differing resuscitation fluid strategies suggested that the use of higher ratios of fresh frozen plasma to packed red blood cells may improve outcomes. Similar results have been seen in other retrospective studies and a few small prospective cohort studies, although the retrospective studies are subject to survival bias.

It is also unclear whether the benefit from these strategies comes from the coagulation factors present in fresh frozen plasma or from reducing the amount of crystalloid and colloid administered. Nevertheless, it seems clear that the usual 1-2 units of plasma previously administered after massive transfusions was insufficient to prevent dilutional coagulopathy. Current consensus is that plasma should be given from the beginning of the resuscitation, alongside transfusions of packed red blood cells, in a ratio of 1 unit of plasma for each 1-2 units of packed red blood cells. Very little is known about platelet function in trauma induced coagulopathy or the effectiveness of platelet transfusions. Although these early strategies of blood product in high doses seem effective, they are based on limited evidence. These regimens also place substantial resource demands on blood banks and are logistically difficult to implement owing to the requirements for rapid thawing and delivery.

Research is also being undertaken to look at alternatives to blood component therapy for the management of trauma induced coagulopathy. Fibrinogen is the central substrate of blood clotting, and levels are low in this patient group. Some retrospective evidence suggests that patients who receive more fibrinogen replacement (in the form of cryoprecipitate and plasma) have better outcomes in terms of total use of packed red blood cells and mortality. Fibrinogen is also available as a powdered concentrate and could be a replacement therapy that can be easily administered in trauma induced coagulopathy.

**How do I identify patients with trauma induced coagulopathy?**

Standard clotting tests from laboratories such as the prothrombin time do not show any of the key derangements in trauma induced coagulopathy, such as reduced clot strength and fibrinolysis. Furthermore, in a trauma setting, it is impractical to wait for tests that can take up to 1 hour to process. The point of care versions of these tests (such as the prothrombin time) are prone to be under-read in the presence of low haematocrits. These difficulties have led to a renewed interest in the use of thromboelastography—a point of care assessment of clot generation, strength, and breakdown. This procedure has the potential to provide a rapid assessment of the whole clotting process, but it has not yet been validated in the acute setting. In the absence of a validated diagnostic test at the point of care, management is therefore blind to the status of the coagulation system and relies on clinical judgment and empiric therapy.

**What fluids should be used to resuscitate trauma patients who do not need DCR?**

Patients who do not need DCR need no immediate resuscitation until definitive imaging has identified the underlying injuries. These patients should be observed carefully for signs of physiological and metabolic deterioration, consequent on disease progression with blood loss, visceral injury, and pericardial or pleural tamponade. Debate continues on the relative merits of colloid or crystalloid based resuscitation strategies, with a recent Cochrane review concluding that there was no evidence that survival was better with one or the other solution.

However, a subgroup analysis of 460 patients with traumatic brain injury (Glasgow coma scale ≤9) from a large randomised controlled trial comparing the safety of albumin in normal saline with normal saline identified a survival advantage in the crystalloid group (33.2% vs 20.4%, P=0.003).

Hypertonic solutions have been proposed to improve cerebral perfusion and reduce cerebral oedema, and have been advocated for resuscitation of patients with traumatic brain injury. A meta-analysis of eight randomised trials identified a survival advantage in this group, but a randomised controlled trial of 229 patients with hypotension and severe traumatic brain injury (Glasgow coma scale ≤9) who received prehospital resuscitation with hypertonic or normal saline had almost identical survival and neurological function six months after injury. Furthermore, a recent randomised controlled trial of prehospital use of hypertonic solutions was terminated by the data and safety monitoring board after randomisation of 1,331 patients, having met prespecified futility criteria. Among patients with severe
traumatic brain injury not in hypovolaemic shock, initial resuscitation with either hypertonic saline or hypertonic saline and dextran, compared with normal saline, did not result in improved neurological outcome or survival at six months. Thus, we suggest the use of crystalloid based fluid administration in this cohort of patients who are less severely injured.

Once haemostasis is achieved, what should be done to ensure adequate resuscitation in severe trauma?

Once haemostasis has been achieved with surgical intervention, fracture splintage or angiography, or the requirement for these interventions identified as not necessary, then definitive resuscitation is required. If patients are resuscitated to normal blood pressure and pulse without further parameters being used to evaluate for tissue hypoxia, over half of patients would be inadequately resuscitated, with increased morbidity and mortality. Resuscitation to targets of oxygen delivery or use is termed goal directed therapy, and good quality evidence from randomised trials indicates that this approach should be used in trauma; indeed, the original evidence for this approach came from trauma studies. What other agents should be used in the initial resuscitation period?

Hyperfibrinolysis is common after trauma, owing to associated hypovolaemic shock and tissue injury. In a recent, large, multinational randomised controlled trial researchers targeted a specific component of trauma induced coagulopathy—hyperfibrinolysis. They showed a reduction in mortality with the use of tranexamic acid, which has antifibrinolytic properties (1 g delivered over 15 min, then 1 g over 4 h, commenced within 3 h of injury). Contributors: TH conceived the review and wrote the introduction, sections of permissive hypovolaemia, resuscitation endpoints, and fluid resuscitation. KT wrote the sections contrasting colloids and crystalloids with hypertonic saline. KB wrote the sections on blood product use and trauma induced coagulopathy. The contributions were correlated by TH, and all authors reviewed the paper. TH is guarantor. Competing interests: All authors have completed the Uniform Competing Interest form at www.icmje.org/coi_disclosure.pdf (available on request from the corresponding author) and declare: no support from any organisation for the submitted work; KB has received unrestricted research funding from Octapharma and Thromboelastometry and has consulted for Haemonetics and Sangart; no other relationships or activities that could appear to have influenced the submitted work.

Cardiopulmonary resuscitation

Jerry P Nolan, consultant in anaesthesia and intensive care medicine, Jasmeet Soar, consultant in anaesthesia and intensive care medicine, Gavin D Perkins, professor of critical care medicine

Cardiorespiratory arrest is the most extreme medical emergency—death or permanent brain injury will ensue unless cardiopulmonary resuscitation (CPR) is started within minutes. Four key interventions—known collectively as the chain of survival and comprising early recognition of cardiac arrest, high quality CPR, prompt defibrillation, and effective post-resuscitation care—improve outcomes. This review covers recent developments in CPR and the evidence supporting them.

What is the incidence and outcome of sudden cardiac arrest?

The global incidence of out of hospital cardiac arrest in adults treated by emergency medical services is 62 cases per 100 000 person years; 75-85% of these arrests have a primary cardiac cause. The reported incidence of out of hospital cardiac arrest and its outcome vary considerably. In Europe, the estimated survival to hospital discharge for such cardiac arrests is 8%. Evidence suggests that survival rates are increasing, mainly because CPR is being attempted more often. The improvement is modest, however, because of the decreasing incidence of ventricular fibrillation and pulseless ventricular tachycardia (25-30% of out of hospital cardiac arrests), which have a better prognosis. A recent high quality observational study from the Netherlands has shown that implantable cardioverter defibrillators account for about a third of this decline. The decline in these rhythms has also been attributed to increased use of β blockers.

Patients having an in hospital cardiac arrest often have multiple comorbidities and the cause of the cardiac arrest is often multifactorial (table 1). According to American registry data, about 200 000 cardiac arrests occur in hospital each year (67 cases per 100 000 person years), with 17.6% of patients surviving to hospital discharge. A quarter of patients present with ventricular fibrillation or pulseless ventricular tachycardia. These patients have better survival to discharge (37.2%) than those with pulseless electrical activity or asystole (survival 11.3%). Early data (unpublished) from the UK National Cardiac Arrest Audit show similar outcomes. Outcomes of in hospital cardiac arrest are probably better than those of out of hospital arrests because the arrests are witnessed and CPR and advanced life support are started promptly.

How are CPR guidelines developed?

Since the 1990s, the International Liaison Committee on Resuscitation has facilitated systematic reviews of CPR science. In 2005 and 2010, the committee published an International Consensus on CPR Science with Treatment Recommendations. The 2010 recommendations involved experts from more than 30 countries who evaluated the findings from 277 systematic reviews based on PICO (population, intervention, comparison, outcome) format questions that had been undertaken over three years. The summary treatment recommendations that came from this rigorous process were used to formulate more detailed practical resuscitation guidelines globally. It has not been possible to produce a single set of global guidelines because of regional variations driven by cultural and economic differences. Nevertheless, the guidelines are sufficiently similar to enable international application of the core interventions. The CPR science review and guideline cycle occurs every five years. The remainder of this review will cover key aspects of the 2010 CPR guidelines and will also highlight new research that may influence future guidelines.

Is cardiac arrest preventable?

The vital signs of patients about to have a cardiac arrest in hospital often deteriorate in the hours preceding the event. A meta-analysis concluded that rapid response systems (that incorporate “tracking” of vital signs and criteria for “triggering” a clinical response) reduce the incidence of cardiac arrests outside of the intensive care unit but do not reduce hospital mortality rates. This might be explained by an increase in the number of do not attempt CPR (DNACPR) decisions.

When should a do not attempt CPR (DNACPR) decision be considered?

CPR has undoubtedly saved many thousands of lives over the years. Successful CPR was first described in groups of patients considered to have “hearts too young to die.”
However cardiac arrest (cessation of heart beat) is also part of the natural dying process. Different countries’ laws and ethics relating to resuscitation, end of life care, and advance decisions (living wills) vary greatly. In the United Kingdom, CPR may be withheld when clinical judgment concludes that CPR will not be able to restart the patient’s heart and breathing and restore circulation; the benefits of CPR are agreed to be outweighed by the burdens and risks after careful discussion with the patient (or those close to the patient); a patient has an advanced decision (living will) or makes an informed decision to refuse CPR. 

A recent National Confidential Enquiry into Patient Outcome and Death reviewed more than 700 in hospital cardiac arrests in the UK. The report found that most patients receiving CPR were elderly, frail, and had multiple comorbidities.1 Of the 230 cases for which assessors could form an opinion, they considered resuscitation on clinical grounds would be futile in 196 (85%). The report rightly calls for increased involvement of consultants in decisions on CPR among patients admitted to hospital. Better linkage with community DNACPR decisions is also needed.

How is CPR started?
In adults, CPR is started with 30 chest compressions followed by two ventilations (see table 2 for summary of resuscitation interventions based on age). Continue to alternate chest compressions and ventilations (30:2) until a tracheal tube or a supraglottic airway device (see below) has been inserted, then continue ventilation at 10 breaths per minute while compressing the chest continually.

Animal data and evidence from observational clinical studies indicate that the quality of CPR strongly influences blood flow and outcome. The European Resuscitation Council currently recommends 100-120 chest compressions of 5-6 cm depth per minute (“push hard and fast”); pressure should be fully released between chest compressions and interruptions minimised. 

A recent observational clinical study found that the highest rates of return of spontaneous circulation were associated with chest compression rates of about 125 per minute; however, other studies have shown that compression depth becomes too shallow at rates of more than 120 per minute.13-15 On the basis of all the available data, the optimal compression rate is 120 per minute.13-15

The proportion of time during which chest compressions are performed in each minute of CPR (the chest compression fraction) is independently associated with better survival after out of hospital cardiac arrest caused by ventricular fibrillation: in one observational study a chest compression fraction of 61-80% was associated with the highest survival rate.4

*Data from the United States National Registry of Cardiopulmonary Resuscitation.*
Compression only CPR is clearly better than no CPR, and this was the primary message in high profile media campaigns in the UK and the United States that target people untrained in CPR.\textsuperscript{w32 w33}

Can the quality of CPR be improved?
The quality of CPR can be improved with the use of CPR prompt and feedback devices. These vary in sophistication—from simple metronomes that guide compression rate, to modified defibrillators that monitor compression depth and rate from an accelerometer placed on the chest and ventilation volume and rate by measuring changes in transthoracic impedance. Audio and visual feedback to rescuers are given in real time and data can be stored for later review during debriefing.\textsuperscript{w27} A systematic review of prompt and feedback devices concluded that during training they improve the acquisition and retention of skills, and that they improve the quality of CPR in clinical practice, but there is no evidence that they improve patient outcomes.\textsuperscript{w19}

A prospective cluster randomised study showed that real time visual and audible feedback resulted in CPR that more closely matched the guidelines, but patient outcomes were not affected.\textsuperscript{w20}

Mechanical chest compression devices deliver consistent high quality CPR, but meta-analyses have failed to show that they improve patient outcomes.\textsuperscript{w21 w22} The two main devices are the load distributing band (ZOLL Medical Corporation), which comprises a backboard and a disposable chest band that is tightened and loosened 80 times a minute, and a mechanical compression-decompression device (Physio-Control), which incorporates a suction cup that is pushed up and down on the chest by a battery powered piston.

A large multicentre randomised study of the load distributing band (Circulation Improving Resuscitation Care (CIRC) trial) showed that it did not improve survival to hospital discharge compared with high quality manual CPR (presented by L Wik at the Resuscitation Science Symposium, Orlando, Florida, 12-13 Nov 2011). Two ongoing large randomised studies (LINC and PARAMEDIC trials) are evaluating the prehospital use of the mechanical compression-decompression device.

Although existing data do not support the routine use of mechanical devices, they are used in many parts of the world and may have a role in specific circumstances, such as during transport or when access to the patient is limited, such as CPR during percutaneous coronary intervention.\textsuperscript{w23}

What is the role of impedance threshold devices in CPR?
The impedance threshold device augments the negative intrathoracic pressure generated during the decompression phase of chest compression; this increases the return of venous blood, thereby increasing blood flow with the subsequent chest compression. Animal and human studies show that use of these devices improves haemodynamic values compared with standard CPR.\textsuperscript{w30} The devices have a greater haemodynamic effect when used together with active compression-decompression CPR. In an unblinded randomised trial in out of hospital cardiac arrests, the impedance threshold device combined with active compression-decompression CPR improved survival to hospital discharge with good neurological function compared with conventional CPR.\textsuperscript{w31} When compared with a sham valve during standard CPR, use of the impedance threshold device produced no benefit.\textsuperscript{w32} Given these conflicting data and the cost of the single use valve, routine use of these devices is not recommended.

Are manual or automated defibrillators more effective?
Defibrillation using a manual defibrillator or an automated external defibrillator is the only effective treatment for ventricular fibrillation or pulseless ventricular tachycardia cardiac arrest. Current guidelines recommend an energy level of 150 J for the first shock, with subsequent shocks at the same or higher values (up to 360 J) depending on the specific defibrillator. Use of an automated defibrillator does not require specific training (the rescuer simply follows the audiovisual instructions when the device is switched on). Two high quality population based cohort studies show that use of these devices by bystanders doubles survival after out of hospital cardiac arrest.\textsuperscript{w33 w34}

Despite one study showing that shocks from a defibrillator can be delivered without injury to a gloved rescuer who maintains contact with the patient’s chest,\textsuperscript{w25} expert consensus and current guidelines recommend that manual chest compressions are interrupted to enable safe defibrillation.\textsuperscript{w35} When chest compressions are paused the right ventricle dilates and encroaches on the left ventricle—this may prevent the myocardium from contracting effectively even if defibrillation restores coordinated electrical activity.\textsuperscript{w36} One observational study of in hospital cardiac arrest found increased shock success with shorter pre-shock pauses (the interval between stopping compressions and shock delivery; adjusted odds ratio 1.86 for every five second decrease in pre-shock pause).\textsuperscript{w37} In an observational out of hospital cardiac arrest study, survival to hospital discharge decreased by 18% for every five second increase in pre-shock pause up to 40 seconds.\textsuperscript{w38} It should be possible to deliver a shock with a manual defibrillator with no more than a five second interruption to chest compression.\textsuperscript{w39} A strategy to do this safely includes the continuation of chest compressions while the defibrillator is charging, and this is now taught in advanced life support courses (fig 2).

Adapted from Nolan and Soar.\textsuperscript{w40}
What is the best way to manage the airway during CPR? The optimal method for managing the airway during CPR is unknown. Attempting to intubate the trachea can cause serious interruption to chest compressions —longer than one minute in 30% of cases in one high quality observational study of intubation by paramedics.25 Attempted intubation has a high failure rate unless undertaken by highly experienced workers, and it may result in unrecognised oesophageal intubation.26 The routine use of waveform capnography (a monitor that displays exhaled carbon dioxide as a waveform and not just a numerical value or colour) reduces the incidence of unrecognised oesophageal intubation (pulmonary blood flow during CPR is usually insufficient to generate detectable exhaled carbon dioxide). It also provides an early indication of return of spontaneous circulation (sudden increase in end tidal carbon dioxide).27 Some observational studies have documented an association between tracheal intubation and worse survival after out of hospital cardiac arrest.28 Supraglottic airway devices (such as the laryngeal mask airway, i-gel (airway device with a non-inflatable laryngeal cuff, integral bite block, and gastric drain tube, made by Intersurgical), and laryngeal tube) are increasingly being used for resuscitation. Although they are easier to insert, no prospective controlled trials are available to provide data on clinical outcomes compared with intubation. Two recent observational studies found

QUESTIONS FOR FUTURE RESEARCH

Key research studies currently recruiting
- Continuous chest compressions (CCT: ClinicalTrials.gov NCT01372748)
- Randomised comparison of the effectiveness of the Laryngeal Mask Airway Supreme, i-gel, and current practice in the initial airway management of prehospital cardiac arrest: a feasibility study (REVIVE-Airways; ISRCTN18528625)
- Comparison of conventional adult out of hospital cardiopulmonary resuscitation against a concept with mechanical chest compressions and simultaneous defibrillation—LINC study (ClinicalTrials.gov NCT00609776)
- Prehospital randomised assessment of a mechanical compression device in cardiac arrest (PaRAMEDIC; ISRCTN80233942) www.warwick.ac.uk/go/paramedic
- Amiodarone, lidocaine, or neither for out of hospital cardiac arrest caused by ventricular fibrillation or tachycardia (ALPS; ClinicalTrials.gov NCT01020916)
- Therapeutic hypothermia to improve survival after cardiac arrest in paediatric patients—THAPCA-04 (out of hospital) trial (ClinicalTrials.gov NCT00878644)
- Therapeutic hypothermia to improve survival after cardiac arrest in paediatric patients—THAPCA-H (in hospital) trial (ClinicalTrials.gov NCT00880087)
- Target temperature management after cardiac arrest (TTM; ClinicalTrials.gov NCT01020916)
- Prehospital resuscitation intranasal cooling effectiveness survival study (PRINCESS; ClinicalTrials.gov NCT01400373)

OTHER AREAS FOR FUTURE RESEARCH

- What are the optimal methods for acquisition and retention of cardiopulmonary resuscitation skills?
- Does the use of adrenaline in cardiac arrest improve long term neurological outcome? The definitive answer will come only with a large placebo controlled randomised trial
- After the return of spontaneous circulation, does the use of controlled reoxygenation (targeting a specific arterial blood oxygen saturation) improve neurological outcome?

TIPS FOR NON-SPECIALISTS

If someone collapses, is unconscious, unresponsive, and not breathing (or taking occasional gasps):
- 1 Call for help—ensure that an ambulance is coming, and if available an automated external defibrillator
- 2 Start chest compressions—push hard (5-6 cm in an adult) and fast (100-120 times per minute)
- 3 If you are trained, willing, and able to do so, give two ventilations after every 30 compressions
- 4 Do not stop unless the person shows signs of regaining consciousness—such as coughing, opening of the eyes, speaking, or moving purposefully—and starts to breathe normally
- 5, If an automated external defibrillator is available switch on and follow the audiovisual prompts *Do not check for a pulse because this sign is unreliable for confirming cardiac arrest

Does echocardiography have a role during CPR?

Focused echocardiography used during the brief pause for a rhythm check may enable identification of potentially reversible causes of cardiac arrest: pericardial tamponade, pulmonary embolism, and hypovolaemia. A prospective observational study found that the finding of pseudo-pulseless electrical activity (cardiac wall motion seen on echocardiography in a pulseless patient) alters management and is associated with increased survival.

What happens after successful CPR?

Once return of spontaneous circulation is achieved, unless the duration of cardiac arrest has been very short, patients will be comatose for variable periods and most will develop the post-cardiac arrest syndrome, which comprises post-cardiac arrest brain injury, post-cardiac arrest myocardial dysfunction, the systemic ischaemia-reperfusion response, and any persistent precipitating pathology. Coronary artery disease is the most common cause of out of hospital cardiac arrest, and many of these patients will require urgent coronary angiography and percutaneous coronary intervention. The increasing use of urgent percutaneous coronary intervention in this situation is driving the treatment of these patients in regional cardiac arrest centres. Table 3 describes interventions to optimise outcome.

A systematic review of nine prospective studies, three follow-up of untreated control groups in randomised controlled trials, 11 retrospective cohort studies, and 47 cases series concluded that the quality of life in survivors who leave hospital is generally good, although they may have psychological and cognitive problems. The wide range in the type and timing of the neurological assessments used in the studies make it impossible to provide specific summary data. It is generally accepted that long term assessments should not be made until at least six months, and preferably one year, after cardiac arrest. Studies documenting these long term neurological cannulation with injection of drugs (including adrenaline) versus neither until return of spontaneous circulation. The other study compared adrenaline with placebo. Both studies found increased rates of return of spontaneous circulation with adrenaline but no difference in survival to hospital discharge. Post hoc analysis of one of these trials showed that patients who received adrenaline had better short term outcomes but an overall decrease in survival to discharge (odds ratio 0.52, 95% confidence interval 0.29 to 0.92; P=0.024) and worse neurological outcomes. In an observational study of 417 188 out of hospital cardiac arrests in Japan, after adjustment for potential confounders, use of adrenaline was associated with a return of spontaneous circulation rate 2.5 times higher but a one month survival rate roughly half of that in those not given adrenaline. Similar findings have been seen in North American and Swedish registry data. Animal data indicate that, although adrenaline improves global cerebral blood flow during CPR, flow in the microcirculation is reduced. This might account for the failure of adrenaline to convert the higher return of spontaneous circulation rates into better long term survival. The uncertainty should be resolved through a large randomised placebo controlled trial. Until such a trial is completed, current guidelines recommend that adrenaline is given every three to five minutes during cardiac arrest (adults 1 mg; children 10 μg/kg; fig 3).

Does echocardiography have a role during CPR?

Focused echocardiography used during the brief pause for a rhythm check may enable identification of potentially reversible causes of cardiac arrest: pericardial tamponade, pulmonary embolism, and hypovolaemia. A prospective observational study found that the finding of pseudo-pulseless electrical activity (cardiac wall motion seen on echocardiography in a pulseless patient) alters management and is associated with increased survival.

What happens after successful CPR?

Once return of spontaneous circulation is achieved, unless the duration of cardiac arrest has been very short, patients will be comatose for variable periods and most will develop the post-cardiac arrest syndrome, which comprises post-cardiac arrest brain injury, post-cardiac arrest myocardial dysfunction, the systemic ischaemia-reperfusion response, and any persistent precipitating pathology. Coronary artery disease is the most common cause of out of hospital cardiac arrest, and many of these patients will require urgent coronary angiography and percutaneous coronary intervention. The increasing use of urgent percutaneous coronary intervention in this situation is driving the treatment of these patients in regional cardiac arrest centres. Table 3 describes interventions to optimise outcome.

A systematic review of nine prospective studies, three follow-up of untreated control groups in randomised controlled trials, 11 retrospective cohort studies, and 47 cases series concluded that the quality of life in survivors who leave hospital is generally good, although they may have psychological and cognitive problems. The wide range in the type and timing of the neurological assessments used in the studies make it impossible to provide specific summary data. It is generally accepted that long term assessments should not be made until at least six months, and preferably one year, after cardiac arrest. Studies documenting these long term neurological
outcomes generally report that more than 85% of patients have a “good” outcome defined by a cerebral performance category of 1 or 2 (online appendix). Category 2 is described broadly as “disabled but independent” and includes patients with hemiplegia, seizures, and permanent memory changes. This system provides only a crude measurement of neurological outcome; studies that use much more sensitive tests of memory and cognition generally show subtle cognitive deficits in most survivors of cardiac arrest.a42,a43

How should we teach CPR?

The ability to recognise cardiac arrest and deliver CPR is an essential skill for all healthcare professionals. Knowledge and skills in this area can deteriorate within three to six months after training. Frequent assessments and, when needed, refresher training, are recommended to maintain knowledge and skills. Properly validated short video and online self instruction courses with hands on practice are an effective alternative to instructor led basic life support skills.a44 A large randomised controlled trial showed that the costs of training can be reduced if courses that combine e-learning and face to face training are used.a45

Prehospital management of severe traumatic brain injury

Clare L Hammell, specialist registrar anaesthesia and intensive care medicine¹ ³, J D Henning, consultant anaesthesia and intensive care² ³

Traumatic brain injury is a substantial cause of morbidity and mortality in the UK. An estimated 11 000 people per year sustain a severe traumatic brain injury, mostly between ages 15 and 29 years.¹ Patients with severe traumatic brain injury have a high mortality rate (30-50%) and many survivors will have persistent severe neurological disability.² Prompt identification and appropriate early management of traumatic brain injury is essential to optimise outcome, however, few guidelines are available for clinicians on management in the challenging prehospital environment. The 2007 report by the national enquiry into patient outcome and death on the provision of trauma services in the UK³ highlighted concerns about prehospital management of airways and ventilation in 15% of patients with severe head injuries. Doctors from various hospital specialties or general practice may be involved in providing prehospital care, so this review aims to provide a generic overview of available evidence on management of severe traumatic brain injury in adults in this environment.

What is the pathophysiology of severe traumatic brain injury?

Severe traumatic brain injury is defined as a head injury resulting in a Glasgow coma score of less than 9.⁴ Primary brain injuries that can occur at the time of impact include extradural and subdural haematoma, intracerebral contusions, and diffuse axonal injuries. Additional insults such as hypoxaemia, hypotension, or hyperpyrexia result in further cerebral damage and secondary brain injury. Modern management of head injuries focus on the identification and treatment of such potential secondary insults.

What are the priorities in prehospital management of severe traumatic brain injury?

Rapid patient transfer to an appropriate secondary care facility is essential, in addition to the implementation of measures to prevent secondary brain injury. Epidemiological studies show that a third of patients with severe traumatic brain injury already have a documented secondary brain insult on hospital admission.⁵ Prehospital management of these patients focuses on provision of an adequate airway, effective oxygenation and ventilation, maintenance of an adequate cerebral perfusion pressure and avoidance of further increases in intracranial pressure. Two retrospective reviews found improved outcomes in patients with severe head injuries when these parameters were specifically targeted in the prehospital setting.⁶ ⁷ Box 1 lists problems that may be encountered during extrication of the patient from a vehicle (figure).

What are the options for airway management?

Airway compromise is common after severe traumatic brain injury and has an important contribution to the development of secondary brain injury. Basic airway adjuncts are used initially and high flow oxygen is administered. Controlled trials of simulated prehospital scenarios⁸ have shown that laryngeal mask airways have a greater success rate for establishing an airway than endotracheal intubation, particularly with inexperienced clinicians. Laryngeal mask airways are becoming increasingly popular in prehospital care for airway maintenance, particularly in situations where access to the patient is limited. The devices are easy to insert, usually provide a good seal within the oropharynx, and provide airway protection from upper airway secretions. Regurgitation and aspiration of gastric contents remains a risk, but may be reduced with the use of alternative laryngeal masks such as LMA Pro-Seal.

SOURCES AND SELECTION CRITERIA

We searched Medline 1980-2008, Pubmed and the Cochrane library for clinical trials and reviews. The medical subject headings “head injury”, “brain injury”, “trauma”, “prehospital”, and combinations thereof were used. Individual therapeutic options (such as “mannitol”) were also searched for. Search results were individually reviewed and manually cross referenced. Reference lists were searched for additional works. Priority was given to review articles, meta analyses, and well designed large trials. The websites www.braintraumafoundation.org, www.trauma.org, and www.east.org were also searched for additional information.

SUMMARY POINTS

- Management of severe traumatic brain injury is focused on rapid transfer to secondary care while preventing secondary brain injury
- Airway compromise and inadequate ventilation are common and should be addressed immediately
- Prehospital endotracheal intubation should be undertaken with the assistance of anaesthetic drugs by appropriately trained physicians
- Hypotension is an independent risk factor for mortality; small boluses of isotonic crystalloid fluids should be given if it occurs
- Patients may be best managed in a neurosurgical centre where they should receive definitive neurosurgical treatment within 4 hours of injury
- There is no role for the routine use of corticosteroids in patients with head injury
Endotracheal intubation is inevitably required in almost all patients with severe traumatic brain injury, although evidence for its benefit in the prehospital environment is controversial. Most studies are retrospective and study paramedics performing endotracheal intubation with minimal use of sedative agents and muscle relaxants. Several large retrospective reviews have, however, shown that this approach results in a high risk of complications, such as failed intubation and hypoxaemia. Laryngoscopy without the use of anaesthetic agents is particularly damaging in patients with traumatic brain injury because increases in intracranial pressure are not attenuated; this may explain the association between prehospital endotracheal intubation and increased mortality and poor neurological outcome in patients with severe traumatic brain injury, which was reported in two retrospective analyses of trauma registries.

Data about true rapid sequence induction of anaesthesia performed by physicians are more promising. A recent retrospective analysis of prehospital rapid sequence induction procedures in the UK reported low incidences of complications, and similar studies have reported intubation success rates of 94-97%, in addition to low complication rates for prehospital drug assisted intubation. These data suggest that prehospital rapid sequence induction is beneficial if done by an appropriately trained physician; this finding is in line with recommendations from the recent trauma report from the national enquiry into patient outcome and death (box 2). With few doctors present at the scene of emergency situations, only a few patients with severe traumatic brain injury are intubated before hospital transfer in the UK, although at least half of all these patients need intubation within 30 minutes of arrival at the hospital. A few patients, for example, those with severe facial trauma, may however require a primary surgical airway.

Which anaesthetic agents should be used to facilitate intubation?

Administering anaesthetic and neuromuscular blocking drugs to facilitate intubation leads to improved outcomes in patients with head injuries. Ideal agents should have minimal effects on heart rate and blood pressure and reduce intracranial pressure while maintaining cerebral perfusion. Etomidate results in a low incidence of hypotension when used to facilitate intubation in patients with head injury and is perhaps the most widely used drug despite concerns about inhibition of steroid synthesis after a single dose.

Ketamine has usually been avoided in patients with head injuries, but a review of randomised clinical trials concluded that with controlled normocapnic ventilation, ketamine has minimal or favourable effects on intracranial pressure in sedated patients with head injury. Ketamine has also been associated with maintenance of better cerebral perfusion pressure compared with other sedative agents. After intubation, adequate sedation and neuromuscular blockade must be provided for all patients during transfer to avoid rises in intracranial pressure associated with coughing.

How should patients with severe traumatic brain injury be ventilated?

Hypoxaemia is common after severe traumatic brain injury and prospective studies show an association with increased mortality rate and poorer neurological outcome. Hypoxaemia is usually multifactorial in patients with such injury and the presence of serious chest injuries—for example, haemopneumothorax or pulmonary contusions—needs to be considered. Hypercapnia is a common consequence of respiratory depression leading to cerebral vasodilatation, increased cerebral blood flow, and a rise in intracranial pressure. One argument in favour of performing rapid sequence induction before transfer to hospital is that this approach allows carbon dioxide levels to be controlled. Hyperventilation leads to cerebral vasoconstriction and ischaemia and should be avoided in patients with head injuries. A large retrospective review reported that 18% of head injured patients were hypocapnic after prehospital intubation with a worse outcome in the group that had a PaCO₂ of less than 4 KPa on admission to the emergency department. A well conducted prospective randomised study showed that monitoring end-tidal carbon dioxide reduced the incidence of hyperventilation by more than 50%. End tidal monitoring of carbon dioxide is now considered a routine standard of monitoring for all mechanically ventilated patients during transfer. Box 3 describes additional monitoring standards.

How should circulatory complications be managed?

Patients with severe traumatic brain injury who are hypotensive have a doubled risk of mortality compared with normotensive patients. Hypotension results in reduced cerebral perfusion and neuronal ischaemia and is often multifactorial in origin in trauma patients. It is best to assume that hypotension is due to hypovolaemia until proven otherwise. Cerebral perfusion pressure (CPP) is calculated by subtracting intracranial pressure from the mean arterial pressure. Maintaining a CPP of 60-70 mm Hg is an essential foundation of hospital management of severe traumatic brain injury. However, measuring an accurate mean arterial pressure is difficult in the prehospital environment so most guidelines use the systolic value as a target during the resuscitation phase.

The Brain Trauma Foundation recommends a minimum systolic pressure of 90 mm Hg in adults with severe head injuries. This target is based on prospectively collected large datasets showing that a systolic blood pressure of less than 90 mm Hg is an independent risk factor for mortality after severe traumatic brain injury. No studies have been done to assess the effects of aiming for values higher than 90 mm Hg, although this approach is probably desirable in patients with isolated severe traumatic brain injury. In patients with multiple injuries and hypovolaemia a conflict exists between these recommendations and the need to maintain adequate cerebral perfusion pressure. Hypertension may be used to maintain adequate CPP if patients are haemodynamically unstable, or if it is difficult to achieve CPP targets using the above methods. At least 100 mm Hg systolic pressure is recommended in patients with multiple traumatic injuries in whom hypotension may result in further worsening of brain injury.

---

**BOX 1 PROBLEMS ENCOUNTERED DURING EXTRICATION FROM A VEHICLE**

- Multiple hazards in and around the vehicle
- Difficulty with patient assessment due to noise level
- Physical entrapment of patient
- Limited access for interventions
- Poor communication between various agencies involved
- Time pressure

---

**BOX 2 INDICATIONS FOR PREHOSPITAL RAPID SEQUENCE INDUCTION OF ANAESTHESIA (GREAT NORTH AIR AMBULANCE STANDARD OPERATING PROTOCOL)**

- Airway problems that cannot reliably be managed by simple manoeuvres, such as severe facial injury
- Respiratory insufficiency (SpO₂ <92%) despite 15 l/min oxygen or impending respiratory collapse due to exhaustion or pathology
- Glasgow coma scale <9 or rapidly falling
- Patients at risk of respiratory deterioration when access is difficult during transfer to definitive care (for example, those with facial burns)
- Patients needing sedation before transfer to hospital because they present a danger to themselves or attending staff, or for humanitarian reasons (for example, to provide complete analgesia)
End-tidal carbon dioxide monitoring is essential for the transfer of ventilated patients.

Oxygenation and blood pressure should be measured as often as possible and should be monitored continuously if possible.

Systolic blood pressure and diastolic blood pressure should be measured with the most accurate method available.

Box 3: Guidelines for Monitoring Patients with Severe Traumatic Brain Injury in the Prehospital Environment

- Patients with suspected severe traumatic brain injury should be monitored in the prehospital setting for hypoxaemia (arterial desaturation <90%) or hypotension (systolic blood pressure <90 mm Hg).
- Blood oxygen saturation should be monitored continuously in the field with a pulse oximeter.
- Systolic blood pressure and diastolic blood pressure should be measured with the most accurate method available.
- Oxygenation and blood pressure should be measured as often as possible and should be monitored continuously if possible.
- End-tidal carbon dioxide monitoring is essential for the transfer of ventilated patients.

Box 4: Recommendations for Management of Head Injury

- Prehospital assessment of neurological status should be done in all cases where head injury is apparent or suspected, using the Glasgow coma scale. Pupil size and reactivity should also be recorded.
- A pre-alert should be made for all trauma patients with a Glasgow coma scale less than or equal to 8, to ensure appropriately experienced professionals are available and to prepare for imaging.
- Patients with severe head injury need early definitive airway control and rapid delivery to a centre with onsite neurosurgical service. This requires regional planning of trauma services, including prehospital physician involvement.
- Patients with severe head injury should have a CT scan as soon as possible after admission and within an hour of arrival at hospital.
- All patients with severe head injury should be transferred to a neurosurgical or critical care centre irrespective of need for surgical intervention.

Between “permissive hypertension” resuscitative strategies to minimise blood loss and the need to maintain an adequate cerebral perfusion pressure to prevent secondary brain injury. The ideal resuscitation fluid is unknown for patients with severe traumatic brain injury. A well conducted large multicentre randomised controlled trial found a relative risk of death of 1.8 in patients with such injuries in intensive care who were resuscitated with albumin compared with 0.9% saline. This finding has led guidelines to recommend use of small boluses of isotonic crystalloid to correct hypotension in patients with severe traumatic brain injury. Hypertonic crystalloid solutions may have a future clinical role in this subgroup. A meta-analysis of randomised, double-blinded controlled trials found improved survival rates in patients with head injury who were resuscitated with hypertonic saline and dextran solutions compared with those who received standard care. Currently the use of hypertonic solutions is not widespread in prehospital care in the UK.

What treatments can be used to reduce intracranial pressure?

Intracranial pressure is often raised in patients with severe traumatic brain injury and specific treatment should be given to lower it if clinical signs are present (for example, pupillary dilatation) and if transfer time allows. Hypoxaemia, hypotension, hypercapnia, and inadequate sedation (in an intubated patient) should all be addressed before specific treatment. Little data is available about strategies to reduce intracranial pressure in the prehospital environment. A recent Cochrane review reported a relative risk of death of 0.8 when mannitol was used to reduce intracranial pressure compared with standard care in hospital, but it concluded that there was insufficient data to support prehospital administration of the drug. Hypertonic saline can be used as an alternative to mannitol; studies directly comparing the drugs’ capacity to lower intracranial pressure have yielded conflicting results. A large randomised prehospital trial of hypertonic saline in traumatic brain injury is about to begin recruiting.

What is the role of corticosteroids in patients with severe traumatic brain injury?

Owing to the findings of a large randomised controlled trial published in 2004, which showed a significant increase in the risk of death in patients randomised to receive corticosteroids, routine use of corticosteroids is no longer recommended for patients with head injury.

How should patients with severe traumatic brain injury be immobilised?

The presence of a head injury is the strongest independent risk factor for injury of the cervical spine. In patients with severe traumatic brain injury, an assumption of spinal injury should be made and full spinal immobilisation should be implemented as early as practically possible in the field. Early assessment of the cervical spine should be done after transfer to hospital to avoid the risk of intracranial hypertension associated with hard cervical collars. In sedated and paralysed patients the use of sandbags and tape may achieve better immobilisation than rigid cervical collar.

Is hypothermia beneficial?

There is little doubt that hyperpyrexia is detrimental to outcome after severe traumatic brain injury, but the role of induced hypothermia in severe head injury is unclear. Early randomised controlled trials showed benefits in outcome for hypothermia as a treatment for refractory intracranial hypertension in patients with severe traumatic brain injury, but subsequent meta analyses have not confirmed this benefit. One randomised trial showed improved neurological outcome at six months in younger patients (younger than age 45 years) who arrived at hospital with a low body temperature, which was then maintained, suggesting that patients with severe traumatic brain injury who are cold should not be actively rewarmed. This observation must be considered in relation to the fact that hypothermia is a key factor in the development of traumatic coagulopathy in patients with multiple injuries.

Should patients with traumatic brain injury be transferred directly to a neurosurgical centre?

A recent retrospective analysis showed a reduction in mortality in patients with head injuries managed in neurosurgical centres and concluded that all patients with severe traumatic brain injury should be managed in such centres (box 4). Although this review was large, it only included data from about two thirds of institutions in the UK and may have been subjected to a triage bias because patients with very severe injuries are not usually accepted for treatment in neurosurgical centres. Currently, in the UK, neurointensive care beds are insufficient to manage all patients with severe traumatic brain injury and so a substantial proportion will still be treated in non-specialist centres. The presence of other injuries to the patient, mode of transport and proximity to institutions should all be considered when deciding which secondary care facility is appropriate.

Conclusion

Severe traumatic brain injury is common and often results in a poor neurological outcome. Outcomes can be improved if patients receive definitive treatment for their head injury as soon as possible after injury, preferably in a neurosurgical centre. Hypoxaemia and hypotension are common in these patients and together result in a mortality rate of more than 75%. Careful identification and treatment of these factors can reduce the development of secondary brain injury.
TIPS FOR NON-SPECIALISTS

- Airway obstruction is common in these patients but can usually be managed initially with simple manoeuvres and adjuncts
- Focus on the basics, ensuring adequate oxygenation and ventilation
- Do not delay patient extrication by performing unnecessary interventions
- Transfer rapidly to secondary care

Management of the effects of exposure to tear gas

Pierre-Nicolas Carron, specialist in internal and emergency medicine, Bertrand Yersin, professor of emergency medicine

Despite the frequent use of riot control agents by European law enforcement agencies, limited information exists on this subject in the medical literature. The effects of these agents are typically limited to minor and transient cutaneous inflammation, but serious complications and even deaths have been reported. During the 1999 World Trade Organisation meeting and at the 2001 Summit of the Americas in Quebec, exposure to tear gas was the most common reason for medical consultations. Primary and emergency care physicians play a role in the first line management of patients as well as in the identification of those at risk of complications from exposure to riot control agents. In 1997 the National Poisons Information Service in England received 597 inquiries from doctors seeking advice about problems related to crowd control. Our article reviews the different riot control agents, including the most common tear gases and pepper sprays, and provides an up to date overview of related medical sequelae.

Sources and selection criteria
We searched the following for relevant information on the medical toxicity and management of acute exposure to tear gas and pepper spray: Medline, PreMedline, Embase, CINAHL, SCIRUS, the Cochrane Library, ISI Web of Knowledge, Toxnet, Google Scholar, and personal archives. We used the subject headings “riot control agents”, “pepper spray”, “lacrimator”, “tear gas”, “irritants”, “incapacitating agents”, as well as the toxicological terms “cholorobenzylidene-malononitrile”, “chloroacetophenone”, “dibenzoxazepine”, “chlorodiphenylarsine”, and “capsaicin”. We also searched the reference lists for additional articles. The overall evidence supporting the current therapeutic approach to patients exposed to tear gas or pepper spray is of poor quality.

What is a tear gas?
Tear gases (along with pepper sprays, toxic emetics, and some sedative substances) are among the so called riot control agents. A tear gas is actually not a gas at all, but a toxic chemical irritant in the form of powder or drops mixed to variable concentrations (1%-5%) in a solvent, and delivered with a dispersion vehicle (a pyrotechnically delivered aerosol or spray solution). Tear gases are not currently considered as chemical weapons by Western countries. Since the 1950s, they have been mainly used by law enforcement agencies for crowd control purposes in most European countries, including the United Kingdom, France, Germany, and Switzerland. Tear gases are also used in military training exercises to test the rapidity or efficacy of protective measures in the event of a chemical attack.

Of the known disabling chemical irritants (of which there are more than a dozen), the five that are traditionally used in the European Union are chlorobenzylidene-malononitrile (also known as CS, after the chemists Corson and Stoughton who first synthesised it), chloroacetophenone (CN or “Mace”), dibenzoxazepine (CR), oleoresin capsicum (OC), and pelargonic acid vanillylamide (PAVA) (fig 1). Diphenylylaminochloroarosine (DM or adamsite) is an irritating and harassing arsenic based agent used in some countries outside the EU. Oleoresin capsicum is a mixture of cayenne pepper extracts, of which capsaicin is the main active ingredient. Its concentration varies from 1% to 15% depending on the mixture. Pepper strength is measured in Scoville heat units, ranging from zero for green pepper to 15 million units for pure capsaicin. Pelargonic acid vanillylamide is a new standardised synthetic variant of oleoresin capsicum used mainly in Switzerland, Austria, and Germany. How do riot control agents work?
The irritant effects of crowd control agents probably result from the action of chlorine or cyanide groups in addition to alkalisng compounds (fig 1). These agents interact with muco-cutaneous sensory nerve receptors such as TRPA1 cation channels. The effect of oleoresin capsicum is linked to a direct stimulation of type C and AD sensory nerve endings, provoking an immediate release of the inflammatory P substance. A toxic effect of the solvent methyl-isobutyl-ketone or of certain metabolites has also been documented in animal experimental studies, in particular for chlorobenzylidene-malononitrile (formation of cyanide and thioulsol derivatives) and chloroacetophenone (formation of hydrogen chloride).

Assessments of the effects of riot control agents must take into account the weather (wind, rain, and ambient temperature) in addition to the characteristics of the site of deployment (open or closed space) as the effects of tear gas are enhanced by heat and by high ambient humidity. Characteristics common to all agents include a rapid onset time and a short duration of effects, as well as a wide margin of safety between the incapacitating dose (IC50, the concentration (C) that causes incapacitation (I) in 50% of individuals after one minute (t=time)) and the lethal dose (LC50, the concentration that causes death (L) in 50% of individuals after one minute). The agents differ from one another by their duration of action, their toxicity (chloroacetophenone and diphenylaminochloroarosine are more toxic than chlorobenzylidene-malononitrile or dibenzoxazepine), and their physical and chemical characteristics (table 1). Current information on toxicity is largely based on in vitro and animal studies.

**SUMMARY POINTS**

- Tear gas and pepper spray used for crowd control are not without risks, particularly for people with pre-existing respiratory conditions
- Pulmonary, cutaneous, and ocular problems can result from exposure to these agents
- Treatment for the effects of exposure to tear gas requires chemical decontamination, including protective measures for healthcare staff
- Some people are at risk of delayed complications that can be severe enough to warrant admission to hospital and even ventilation support
What are the medical consequences of acute exposure to tear gas and pepper spray?

There is limited human research on the risks of tear gas in terms of inducing disability or death. The irritant effect of tear gases affects exposed cutaneous and mucous membrane surfaces. Table 2 summarises the medical complications. Clinical experience and retrospective case studies suggest that the cutaneous effect is by far the most serious symptom, including first and second degree burns. Even in minor cases, skin erythema can last several hours. Direct contact with the flame or a hot canister increases the risk of severe lesions. Delayed contact allergy, leukoderma, or exacerbation of pre-existing dermatitis have also been described in case reports.

In experimental studies, transient conjunctivitis and blepharospasm occurred a few seconds after exposure and varied with the concentration of the agent and the duration of exposure. Corneal damage, hyphema, or vitreous haemorrhage have been described in isolated cases. Case studies indicate that shortness of breath, sore throat, and chest pain are the most common pulmonary complaints, and these typically resolve within 30 minutes. Some authors have also reported bronchospasm and laryngospasm. Delayed pulmonary oedema has been described in recent case studies, but permanent long term lung damage seems improbable.

Several cases of death have been attributed to the use of chloracetophenone in confined spaces. Some of the deaths in the 1993 siege on the Branch Davidians in Waco, Texas, were attributed to the use of large amounts of chlorobenzylidene-malononitrile in a confined space.

With pepper sprays, the irritant effect is immediate and lasts 30 minutes on average, mainly affecting the eyes, skin, and respiratory tract. Minor side effects (corneal erosion, respiratory irritability) are described in many case reports. The rare deaths that have been documented were caused by bronchospasm, pulmonary oedema, or respiratory arrest and occurred mainly in patients with asthma. Capsaicin also has neurotoxic and skin desensitising effects (hence its use in treating refractory pain) and animal studies indicate it may play a role as a procarcinogen after repeated cutaneous or digestive system contact.

Avoidance of exposure and initial management of people exposed to tear gas

The best way for people (including medical staff) to avoid exposure to crowd control agents is obviously not to enter areas that pose a risk of exposure and to move away from these areas quickly if such agents are used. However, emergency medical staff do often have to go near or into such areas to treat affected people, so they must protect themselves by avoiding gaseous areas and by staying on higher ground whenever possible. As tear gases are heavier than air, the patient should be lifted off the ground as quickly as possible and the emergency medical vehicles should be parked in higher areas.

In clinical experience, tear gas or pepper spray has caused secondary contamination of healthcare staff as a result of contact with contaminated patients. Therefore, experts recommend that the initial medical management of patients exposed to tear gases should be symptomatic and consist primarily of non-specific chemical decontamination. Identification of affected people and appropriate personal protection (such as clothes gathered at the wrists and neck; gloves; and surgical masks) can prevent secondary contamination of medical staff.

**PRE-EXISTING CONDITIONS AND CHARACTERISTICS OF THE AFFECTED PERSON**

- Asthma
- Chronic obstructive pulmonary disease
- Cardiovascular disease
- Severe hypertension
- Young children
- Patients over 60 years
- Ocular diseases
- Contact lenses

**ENVIRONMENTAL FACTORS**

- Confined space
- Poor ventilation

**AMOUNT AND POTENCY OF EXPOSURE**

- High concentration
- Prolonged exposure
- Repeated exposure
- Potent toxicity of the product (chloracetophenone is more toxic than chlorobenzylidene-malononitrile)

An initial triage allows for identification of at-risk patients, including those with loss of consciousness or with dyspnoea, those of advanced age, those with comorbidities, and those who have had prolonged exposure to the tear gas or pepper spray (box). Medical staff should be aware that there may be particularly serious consequences of exposure, such as respiratory symptoms, bronchospasm, and laryngospasm. Staff should move patients away quickly from the toxic vapours and undress them in a well ventilated area. If contamination is severe, pullovers and T-shirts must be removed by cutting and should not be pulled over the patient’s head. Contaminated clothes must be sealed hermetically in a double plastic bag.

**WHAT IS THE TREATMENT FOR PEOPLE WITH SYMPTOMS OF EXPOSURE?**

How to best manage symptomatic patients is still a matter of debate and is currently based on case series or limited human studies. Eyes should be rinsed for 10-15 minutes and the patient should be sealed hermetically in a double plastic bag.
In rare cases the digestive tract may be affected by ingestion.

nochloroarsine; OC = oleoresin capsicum.

Some tear gases are more likely to induce specific complications (as noted by abbreviations): CN = chloracetophenone; CS = o-chlorobenzylidene malononitrile; CR= dibenzoxazepine; DM = diphenylaminochloroarsine.

*In rare cases the digestive tract may be affected by ingestion.

TIPS FOR NON-SPECIALISTS

• Medical teams should wear protection for their own safety and to prevent secondary contamination.
• Contaminated clothes must be removed; eyes and affected skin surfaces should be cleaned with water.
• For persistent ocular symptoms, ophthalmological assessment is recommended.
• For severe pulmonary symptoms, oxygen therapy, β2-mimetics and ipratropium aerosols may be required.
• For pulmonary symptoms, a 24-48 hour stay in hospital or a discharge home with detailed information about potential complications is recommended.

AREAS FOR FURTHER RESEARCH

• The alleged safety of existing riot control agents and of all future innovations in this field.
• The delayed toxic effects and potential procarcinogenic risk of repeated exposure.
• The effectiveness of decontamination with water (still a matter of debate).
• Development of potential specific treatments and cutaneous therapeutic agents.
• Definition of the safety criteria for riot control agents, and discussion of the “rules of engagement” with law enforcement agencies at local and national levels.

with isotonic sodium chloride (0.9%) and any contact lenses removed. Patients must not touch their face or rub their eyes. Recently, some authors have suggested using air jets to eliminate any remaining particles on the surface of the eye. For persistent symptoms, experts recommend ophthalmological assessment for abrasions. Most experts propose systematic washing of affected skin surfaces with soap and water. Nevertheless, this strategy remains controversial. Chlorobenzylidene-malononitrile dissolved in water is said to intensify the irritation, and in one small study, skin vesication was observed with 0.5 mg of chloroacetophenone but only when the skin was moist. In a limited randomised study, baby shampoo provided no better relief for eye and skin discomfort than water alone. Many decontamination products, such as Diphoterine, are currently being tested for efficacy. However, their cost plus the lack of evidence of effectiveness precludes any proposal for systematic use. Severe skin lesions are treated with the same methods as for an acute irritant dermatitis, by using topical corticoids and antihistamine agents as necessary.

In the event of pulmonary symptoms such as bronchial spasm, short term medical treatment including oxygen therapy, β2-mimetic and ipratropium aerosols may be required. The rare occurrence of delayed pulmonary oedema in patients with pulmonary symptoms has led to some experts recommending a 24-48 hour stay in hospital for observation or a discharge home with detailed information about potential complications and their clinical manifestations. Digestive tract symptoms (table 2) do not pose a big risk and resolve spontaneously, with the exception of rare cases of voluntary or unintentional ingestion, which requires admission to hospital.

What are the ethical considerations?

Medical consequences of the use of riot control agents remain ill defined in terms of morbidity and mortality. In 1998 an editorial in the Lancet demanded a moratorium on the use of such agents so that the potential long term consequences of these substances could be studied further, in particular in the area of carcinogenicity.

In Europe the medical research necessary to justify the use of certain crowd control technologies is absent, lacking, or of poor quality. Currently, alternatives to crowd control agents seem to be even more deleterious for demonstrators as well as for law enforcement agencies. Whether tear gases are innocuous will nevertheless continue to be debated.

Pain management and sedation for children in the emergency department

Paul Atkinson, consultant in emergency medicine, Adam Chesters, specialty registrar in emergency medicine, Peter Heinz, consultant in paediatric medicine

Children commonly present for emergency care with painful conditions and injuries. Further painful, distressing, or unpleasant diagnostic and therapeutic procedures may be necessary during the visit. Emergency clinicians are expected to provide safe and effective analgesia and sedation for children, and provision of such analgesia is a primary audit standard of the College of Emergency Medicine. We provide an overview of published evidence to help clinicians assess, manage, and minimise pain in children presenting to hospital.

How is acute pain best assessed in children?

The assessment of pain is a core feature of most international triage systems. National guidelines suggest that children with moderate or severe pain should be triaged as urgent and should wait no longer than 20 minutes for administration of adequate analgesia.1

Several methods of assessment have been validated for assessing the severity of pain (table 1).2 The ability to indicate the presence of pain emerges at around 2 years of age. Children as young as 3 years may be able to quantify pain using simple validated pain scales,3 such as verbal rating scales, visual analogue scales, and faces scales (figure).4 5 A large observational study found little evidence for using abnormal physiology—such as tachycardia, tachypnoea, and hypertension—to screen for severe pain, although the presence of abnormal physiology may indicate its presence.

In the acute setting, behaviour is the main way that infants and preverbal children communicate their pain.6 Specific distress behaviours such as crying, facial grimacing, certain postures, and inability to be consoled have been associated with pain in young children. Such responses have been incorporated into pain assessment tools for preverbal children. The Children's Hospital of Eastern Ontario pain and sedation for children, and provision of such analgesia is a primary audit standard of the College of Emergency Medicine. We provide an overview of published evidence to help clinicians assess, manage, and minimise pain in children presenting to hospital.

SUMMARY POINTS

- Ensure that children do not experience prolonged or additional pain when presenting for emergency medical care; use a composite assessment tool to assess pain at triage
- Aim to provide effective analgesia at the first attempt—use the appropriate drug, dose, and route; if possible choose painless modes of delivery (nasal route, flavoured syrups)
- Reassess pain scores frequently to ensure that analgesia is effective and allow enough time for it to work
- Use pharmacological and non-pharmacological modalities to manage pain
- Avoid the “routine” use of unnecessary painful invasive procedures
- Use topical, local, and regional anaesthesia along with appropriate safe procedural sedation to avoid further pain

What is the best initial choice of analgesic drug?

Modern emergency practice aims to provide effective analgesia at the first attempt, on the basis of an accurate assessment of the child’s pain.1

Children with all levels of pain will benefit from administration of paracetamol (acetaminophen). A loading dose of 30 mg/kg should be given initially, followed by the maintenance dose as required (10-15 mg/kg every four to six hours; maximum 90 mg/kg in 24 hours; reduce in infants and neonates).8 For severe pain, national guidelines recommend immediate administration of intravenous opiates in combination with oral drugs and the non-pharmacological methods outlined above.8 The use of inhaled or intranasal analgesics can be valuable before intravenous access has been secured. Well designed randomised controlled trials found that intranasal diamorphine and fentanyl are absorbed rapidly across the nasal mucosa.

Search terms used included “pain”, “analgesia”, “sedation”, “children”, and “emergency”.

4. Sources and selection criteria

- The national service framework for children recommends play for children in hospital.9 Play specialists have a key role in providing age appropriate support. Parents and carers should be encouraged to stay with their child and offer reassurance at all times. Having a designated children’s play area—with books, toys, and a television showing children’s programmes—can help to provide distraction and comfort in an unfamiliar and frightening environment.

- The use of dressings, slings, and splints are other simple measures that can provide effective analgesia.10 As well as the physical benefit of dressing a wound or splinting a deformed limb, covering an injury that causes the child distress to look at may provide psychological benefit. Application of cold packs is a standard approach for ligamentous sprains, and pain from insect and marine stings can be treated by applying cold or heat to the affected part. Cold spray and ice packs provide immediate relief, whereas warm water immersion provides longer lasting analgesia.11

and provide initial pain relief comparable to intravenous opiates.\textsuperscript{13}–\textsuperscript{14} Oral drugs have a delayed onset of action and their absorption is more variable than parenteral ones, but they can be given painlessly, have a synergistic effect when used with other analgesics, and are usually more acceptable to parents and children. Oral medication alone is reserved for children with mild to moderate pain. Some analgesics are available as a suppository, but administration by this route may prove unacceptable for parents and may add to the child's distress. Intramuscular administration of pain relief has a limited role in the emergency management of pain in children because the injection is often painful, absorption unpredictable, and the onset of effect slow.

**How can procedures be carried out without causing further pain?**

For a child with a painful condition or injury, further diagnostic or therapeutic procedures may be necessary but can cause additional pain and distress. Simple measures, such as giving a nitrous oxide and oxygen mix (Entonox) to older children or non-nutritive sucking in young infants, can make minor procedures less distressing.\textsuperscript{13}–\textsuperscript{14} A randomised double blind placebo controlled clinical trial found single dose oral sucrose to be safe and effective in reducing the behavioural and physiological pain response to a painful stimulus in preterm infants.\textsuperscript{15}–\textsuperscript{16} For each additional procedure—from needle related to radiological—carefully consider whether the procedure is immediately necessary, and if the available analgesia or psychological techniques (or both) are likely to be sufficient for the child.

For many common minor procedures, less painful alternative techniques are available, which can be combined with the pharmacological and non-pharmacological methods outlined above. For closure of small simple wounds, evidence from randomised controlled trials show that non-invasive alternatives can be as effective as traditional painful procedures. Skin lacerations can be closed with tissue adhesive rather than sutures with similar medium and long term cosmetic results;\textsuperscript{17} similarly, scalp lacerations can be closed using the hair apposition technique, where strands of hair are twisted across the wound and glued together to close the wound.\textsuperscript{18} When necessary, using absorbable sutures prevents the need for future removal.\textsuperscript{19} Comparative clinical studies have shown venous blood gases to be as accurate as the more painful arterial gases for monitoring acid-base status in children with ureaemic acidosis and diabetic ketoacidosis.\textsuperscript{20}–\textsuperscript{22}

Comparative clinical studies have shown venous blood gases to be as accurate as the more painful arterial gases for monitoring acid-base status in children with ureaemic acidosis and diabetic ketoacidosis.\textsuperscript{20}–\textsuperscript{22}

#### Which topical anaesthetics are available for cannulation and venepuncture?

Topical anaesthetic preparations such as EMLA (euteric mixture of local anaesthetics—lidocaine and prilocaine) and Ametop (tetracaine) can be used on intact skin in patients older than one month before minor skin procedures. A recent Cochrane review found that Ametop is superior to EMLA for reducing overall needle insertion pain in children.\textsuperscript{18} Ametop takes 45 minutes to anaesthetise the skin, whereas EMLA takes 60 minutes, and this fact has to be incorporated into the emergency department triage assessment for children deemed likely to need blood tests or venous access. Ethyl chloride (cooler) spray is an alternative for minor cutaneous procedures such as venepuncture, especially when urgent, but its efficacy is unclear.\textsuperscript{19}–\textsuperscript{20}

#### What are the topical, local, or regional anaesthesia options for wounds and injuries?

LAT gel (lidocaine, adrenaline, and tetracaine) is useful in providing anaesthesia for the cleaning and repair of open wounds such as skin lacerations. All simple lacerations of the head, neck, limbs, or trunk of less than 5 cm in length can be considered for exploration and repair using LAT gel rather than local anaesthetic infiltration. Several randomised controlled trials have shown that it has a similar efficacy but is less painful to apply.\textsuperscript{21}
ESSENTIAL RESOURCES AND CONSIDERATIONS FOR PAEDIATRIC PROCEDURAL SEDATION IN THE EMERGENCY DEPARTMENT

• Appropriately trained personnel present:
• Doctor performing sedation (who has received appropriate training and has documented evidence of successful assessment of competency)
• Doctor or practitioner performing procedure
• Children’s nurse (who is familiar with sedation procedure, monitoring, and equipment)
• Appropriate indication—painful procedure needed during this attendance at the emergency department
• Would a general anaesthetic be more appropriate (no immediate need for the procedure)?
• Quiet location, monitoring, and equipment available (standards of monitoring set by Royal College of Anaesthetists and the UK Academy of Medical Royal Colleges and Faculties)
• Any contraindications in anaesthetic history or examination?
• ASA (American Society of Anesthesiologists) class 3, 4, or 5
• Recent last meal (<4 hours) or recent fluid intake (<2 hours)—relative contraindication
• Previous adverse reactions to drugs
• Previously known anaesthetic risk (such as difficult airway)
• Explanation and informed consent from parents or legally responsible adult
• Record of drugs used including dosage and timing
• Record of vital signs before, during, and after sedation
• Record of adverse events and interventions
• Record of safe recovery

A PARENT’S PERSPECTIVE

Lucy, my 8 year old daughter, fell off a trampoline and badly injured her right arm. On arrival at the emergency department, she was screaming in agony with any small movement. The triage nurse recognised her severe pain immediately. A sling was applied and she was brought straight into a cubicle in the paediatric area where a paediatric nurse encouraged me to help Lucy use the gas and air (Entonox). She was then given a strong painkiller (diamorphine) intranasally, without a needle with a bandage with cartoon pictures on it. After her x ray, the consultant explained that Lucy’s arm was broken and needed to be manipulated. He offered us the option of having her sedated there and then. Lucy was moved to another room in the children’s area and was attached to a monitor. She was given a sedative (ketamine) and she did not feel a thing while they sedated there and then. Lucy’s arm was broken and needed to be manipulated. He offered us the option of having her sedated there and then. Lucy was moved to another room in the children’s area and was attached to a monitor. She was given a sedative (ketamine) and she did not feel a thing while they straightened her arm and put it in plaster. Before we went home, the doctor made sure that Lucy had recovered from the sedation and that we had a supply of painkillers to take home.

Commonly used local anaesthetics for infiltration in the emergency department include lidocaine (with or without adrenaline) and bupivacaine. Local nerve blocks (without adrenaline) completely or partially anaesthetise the area supplied by that nerve. Common examples include digital nerve blocks for injuries to the fingers, and the femoral nerve block for femoral shaft fractures. Specific nerve blocks can be performed for minor surgical procedures around the hand, face, and ears. Additional analgesia, procedural sedation, or non-pharmacological techniques can make these procedures more tolerable to the child.

Does procedural sedation have a role in painful emergency procedures in children?

Background and national guidelines

Many procedures performed on children in the emergency department would cause considerable pain and distress without the use of sedation. Common examples include manipulation of a displaced long bone fracture and suturing of complex wounds where the child will not tolerate injection of local anaesthetic or remain still enough for the procedure to be performed effectively and safely. Procedural sedation allows the patient to tolerate unpleasant procedures while independently maintaining airway control, oxygenation, and circulation. Expertise in procedural sedation and analgesia is a core competency for emergency doctors and anaesthetists. In our experience, the key to safe and successful sedation is optimal pain management in the first instance. Sedation is not a replacement for effective pain management. Guidelines and policies approved by the College of Emergency Medicine and the Scottish Intercollegiate Guidelines Network, and a report commissioned by the UK Academy of Medical Royal Colleges and Faculties, support the use of procedural sedation as a safe and appropriate means to facilitate pain and anxiety management during interventional or diagnostic procedures, including emergencies, for all age groups.1-4

Drug options

Substantial evidence supports the use of a variety of agents for procedural sedation by trained emergency doctors in the emergency department (table 2).5-8 In particular, ketamine with its combined sedative and analgesic action has been extensively reviewed. A meta-analysis of more than 8000 cases found the use of ketamine as sole sedative agent to be safe in children aged 2-13 years (1-2 mg/kg racemic ketamine intravenously). Short term side effects include “bad dreams,” vomiting, and ataxia. Risk factors for airway and respiratory adverse events were high intravenous doses and coadministration of anticholinergics or benzodiazepines.9-11 In older children and adults, it is used as an analgesic (0.25-0.5 mg/kg intravenously) to facilitate brief painful interventions and in conjunction with other anaesthetic agents for sedation.5,10 Other drugs commonly used for sedation in children include propofol and combined benzodiazepines and opiates (midazolam and fentanyl).12 Guidelines recommend fasting for three hours before sedation13; however, a prospective observational study has suggested that prolonged pre-sedation fasting is not essential with ketamine.14

QUESTIONS AND AREAS FOR FUTURE RESEARCH

- What are the long term psychological benefits of optimised pain relief for short painful emergency procedures?
- New delivery methods and agents for more immediate analgesia (such as lidocaine lontophoresis, intradermal injection systems)
- How can we implement optimal and age appropriate pain management strategies into daily practice in a busy emergency department?

TIPS FOR NON-SPECIALISTS

Key non-pharmacological interventions

- Ensure assessment and treatment in a quiet, calm, child oriented environment; a friendly non-intimidating manner in the approach of staff; and reassurance and explanation to both child and parents
- Gentile immobilisation and careful dressings alleviate pressure and movement from the site of pain

Topical anaesthesia

- Tetracaine (Ametop) gel can be used from age one month. It acts faster than EMLA. LAT gel (lidocaine, adrenaline, and tetracaine; contains a vasoconstrictor) should be used for open wounds

Intranasal opiates

- Some opiate preparations can be given intranasally. This provides rapid bioavailability for faster analgesic effect without requiring a needle or cannula.**
- Examples include diamorphine 0.1 mg/kg nasal aerosol (0.2 ml) and fentanyl 1-2 μg/kg nasal aerosol

Sedation

- Do not sedate a child unless you are appropriately trained and certified. Do consider the potential benefits of sedation, however, and seek expert help when needed

Avoiding pain

- Consider whether the proposed procedure is necessary; does a less painful option exist? Use sterile strips or tissue adhesive rather than sutures, and venous rather than arterial blood gases

Training and accreditation in procedural sedation in children

The UK Academy of Medical Royal Colleges and Faculties report on safe sedation practice recommends that instruction in procedural sedation be incorporated into training and revalidation programmes, and that a clinical governance framework should deliver local safe sedation procedures in line with guidelines agreed by the relevant national professional body. The box shows typical components of a local guideline. In particular, multidisciplinary team training is recommended to ensure that all staff involved in procedural sedation understand their roles and that staff who administer the sedative are aware of the possible adverse consequences and have the necessary skills to manage such adverse events.

Conclusions

Safe and effective management of pain and anxiety in children is an essential component of modern emergency practice. Pain can be assessed and treated by a variety of pharmacological and non-pharmacological means (table 3). Children who present in pain can be assessed quickly, treated, and frequently reassessed using an evidence based model of care to ensure that the analgesic strategy is effective (table 1). Several psychological techniques can be used to put the child at ease and lessen the perception of pain. Newer methods of drug delivery will help with the administration of analgesia, and the role of safe procedural sedation in the paediatric emergency department will be consolidated.

Central venous catheters

Reston N Smith, specialty registrar in anaesthesia and intensive care medicine¹, Jerry P Nolan, consultant in anaesthesia and intensive care medicine ²

Central venous catheterisation was first performed in 1929 when Werner Frossman, a German doctor, inserted a ureteric catheter into his antecubital vein. He then walked to the radiography department so that the catheter could be guided into his right ventricle using fluoroscopy. Since then, central venous access has become a mainstay of modern clinical practice. An estimated 200 000 central venous catheters were inserted in the United Kingdom in 1994, and the figure is probably even higher today. Clinicians from most medical disciplines will encounter patients with these catheters. Despite the benefits of central venous lines to patients and clinicians, more than 15% of patients will have a catheter related complication. This review will provide an overview of central venous catheters and insertion techniques, and it will consider the prevention and management of common complications.

What are central venous catheters?
A central venous catheter is a catheter with a tip that lies within the proximal third of the superior vena cava, the right atrium, or the inferior vena cava. Catheters can be inserted through a peripheral vein or a proximal central vein, most commonly the internal jugular, subclavian, or femoral vein.

What are the indications and contraindications to central venous catheterisation?
The indications for central venous catheterisation include access for giving drugs, access for extracorporeal blood circuits, and haemodynamic monitoring and interventions (box 1). Insertion of a catheter solely to measure central venous pressure is becoming less common. A systematic review found a poor correlation between central venous pressure and intravascular volume; neither a single central venous pressure value nor changes in this measurement predicted fluid responsiveness. The need for fluid resuscitation can be evaluated using a test of fluid responsiveness, such as the haemodynamic response to passive leg raising.

Most of the contraindications to central venous catheterisation (box 2) are relative and depend on the indication for insertion.

What types of central venous catheter are available and how are they selected?
Four types of central venous catheter are available (table 1): non-tunnelled, tunnelled (fig 1A), totally implantable (fig 1C), and centrally inserted (fig 1B). Specialist non-tunnelled catheters enable interventions such as intravascular temperature control, continuous monitoring of venous blood oxygen saturation, and the introduction of other intravascular devices (such as pulmonary artery catheters and pacing wires). The catheter type is selected according to the indication for insertion and the predicted duration of use (see table 1).

How are central venous catheters inserted?
Central venous catheters are inserted by practitioners from many different medical specialties and by allied medical practitioners. Someone who is trained and experienced in the technique should be responsible for the line insertion and it should be undertaken in an environment that facilitates asepsis and adequate patient access.

At what anatomical site should I insert the central venous catheter?
The site of insertion depends on several factors: indication for insertion, predicted duration of use, previous line insertion sites (where the veins may be thrombosed or stenosed), and presence of relative contraindications. Ultrasound directed techniques for insertion are now the standard of care in the UK. The site of insertion and indication for the catheter will influence infectious, mechanical, and thrombotic complication rates. A Cochrane systematic review of central venous sites and complications concluded that, in patients with cancer and long term catheters, the risk of catheter related complications was similar for the internal jugular and subclavian routes. For short term central venous catheters, this review concluded that the risk of catheter colonisation (14.2% vs 2.2%; relative risk 6.43, 95% confidence interval 1.95 to 21.2) and thrombotic complications (21.6% vs 1.9%; 11.53, 2.8 to 47.5) is higher for the femoral route than for the subclavian one.

In contrast, a meta-analysis documented no difference in the risk of infectious complications between the internal jugular, subclavian, and femoral routes. The ease of imaging of the internal jugular vein compared with the subclavian vein has made the first route more popular for short term access. A Cochrane review found that for short term access, for haemodialysis, the femoral and internal jugular sites have similar risks of catheter related complications, although the internal jugular route is associated with a higher rate of mechanical complications. Recent Kidney Disease Improving Global Outcomes (KDIGO) guidelines recommend, in order of preference, the right internal jugular, femoral, left internal jugular, and subclavian veins for insertion of a short term dialysis catheter.

SUMMARY POINTS

- A wide variety of central venous catheters are used
- Complications related to central venous catheters are common and may cause serious morbidity and mortality
- Several strategies can reduce central venous catheter related morbidity; these are implemented at catheter insertion and for the duration of its use
- Peripheral inserted central catheters have the same, or even higher, rate of complications as other central venous catheters

REFERENCES

1. Central venous catheterisation was first performed in 1929 when Werner Frossman, a German doctor, inserted a ureteric catheter into his antecubital vein. He then walked to the radiography department so that the catheter could be guided into his right ventricle using fluoroscopy. Since then, central venous access has become a mainstay of modern clinical practice. An estimated 200 000 central venous catheters were inserted in the United Kingdom in 1994, and the figure is probably even higher today. Clinicians from most medical disciplines will encounter patients with these catheters. Despite the benefits of central venous lines to patients and clinicians, more than 15% of patients will have a catheter related complication. This review will provide an overview of central venous catheters and insertion techniques, and it will consider the prevention and management of common complications.

2. What are central venous catheters?
A central venous catheter is a catheter with a tip that lies within the proximal third of the superior vena cava, the right atrium, or the inferior vena cava. Catheters can be inserted through a peripheral vein or a proximal central vein, most commonly the internal jugular, subclavian, or femoral vein.

3. What are the indications and contraindications to central venous catheterisation?
The indications for central venous catheterisation include access for giving drugs, access for extracorporeal blood circuits, and haemodynamic monitoring and interventions (box 1). Insertion of a catheter solely to measure central venous pressure is becoming less common. A systematic review found a poor correlation between central venous pressure and intravascular volume; neither a single central venous pressure value nor changes in this measurement predicted fluid responsiveness. The need for fluid resuscitation can be evaluated using a test of fluid responsiveness, such as the haemodynamic response to passive leg raising.

4. Most of the contraindications to central venous catheterisation (box 2) are relative and depend on the indication for insertion.

5. What types of central venous catheter are available and how are they selected?
Four types of central venous catheter are available (table 1): non-tunnelled, tunnelled (fig 1A), totally implantable (fig 1C), and centrally inserted (fig 1B). Specialist non-tunnelled catheters enable interventions such as intravascular temperature control, continuous monitoring of venous blood oxygen saturation, and the introduction of other intravascular devices (such as pulmonary artery catheters and pacing wires). The catheter type is selected according to the indication for insertion and the predicted duration of use (see table 1).

6. How are central venous catheters inserted?
Central venous catheters are inserted by practitioners from many different medical specialties and by allied medical practitioners. Someone who is trained and experienced in the technique should be responsible for the line insertion and it should be undertaken in an environment that facilitates asepsis and adequate patient access.

7. At what anatomical site should I insert the central venous catheter?
The site of insertion depends on several factors: indication for insertion, predicted duration of use, previous line insertion sites (where the veins may be thrombosed or stenosed), and presence of relative contraindications. Ultrasound directed techniques for insertion are now the standard of care in the UK. The site of insertion and indication for the catheter will influence infectious, mechanical, and thrombotic complication rates. A Cochrane systematic review of central venous sites and complications concluded that, in patients with cancer and long term catheters, the risk of catheter related complications was similar for the internal jugular and subclavian routes. For short term central venous catheters, this review concluded that the risk of catheter colonisation (14.2% vs 2.2%; relative risk 6.43, 95% confidence interval 1.95 to 21.2) and thrombotic complications (21.6% vs 1.9%; 11.53, 2.8 to 47.5) is higher for the femoral route than for the subclavian one.

8. In contrast, a meta-analysis documented no difference in the risk of infectious complications between the internal jugular, subclavian, and femoral routes. The ease of imaging of the internal jugular vein compared with the subclavian vein has made the first route more popular for short term access. A Cochrane review found that for short term access, for haemodialysis, the femoral and internal jugular sites have similar risks of catheter related complications, although the internal jugular route is associated with a higher rate of mechanical complications. Recent Kidney Disease Improving Global Outcomes (KDIGO) guidelines recommend, in order of preference, the right internal jugular, femoral, left internal jugular, and subclavian veins for insertion of a short term dialysis catheter.
Technique of inserting a cannula into the internal jugular vein
Box 3 describes in detail the technique for inserting a central venous catheter (fig 3).

Skin preparation
The skin is prepared with a solution of 2% chlorhexidine in 70% isopropyl alcohol. A meta-analysis found a reduction in catheter related infections when chlorhexidine is used instead of povidone-iodine. However, a systematic review has highlighted that many of the studies on this topic have compared chlorhexidine in alcohol with aqueous povidone-iodine. The immediate action of alcohol might combine with the more persistent effect of chlorhexidine to produce optimal antisepsis.

Ultrasound guidance
National Institute for Health and Care Excellence (NICE) guidelines recommend using ultrasound guidance for the elective insertion of central venous catheters into the internal jugular vein in adults and children. A meta-analysis indicates that ultrasound guided placement results in lower failure rates, reduced complications, and faster access compared with the landmark technique. Real time imaging of needle passage into the vessel can be performed out of plane (vessel imaged in the transverse plane) or in-plane (vessel imaged in the longitudinal plane). An international expert consensus group concluded that, although no one technique is better than another, a combination of the two may be optimal. The in-plane technique is technically more challenging but enables the position of the tip of the thin walled needle (or cannula) and the wire to be identified precisely (for example, inadvertent penetration of the posterior wall of the vein will be seen clearly). Although ultrasound imaging of the internal jugular and femoral veins is much easier than imaging of the subclavian vein (the view is obscured by the clavicle), ultrasound guided catheterisation of the subclavian vein is possible with the use of a slightly more lateral approach (initially entering the infraclavicular axillary vein).

What is the optimal location for the tip of the central venous catheter?
Incorrect placement of the catheter tip increases mechanical and thrombotic complications, but the ideal location of the catheter tip depends on the indications for catheterisation and the site of insertion. No single catheter tip position is ideal for all patients. Patients with cancer are at high risk for developing thrombosis. To reduce rates of thrombosis related to long term catheters in these patients, the catheter tip should lie at the junction of the superior vena cava and right atrium, which is below the pericardial reflection and lower than that recommended for other patients. In other patients, expert opinion suggests that the tip should lie parallel to the wall of a large central vein outside of the pericardial reflection. This reduces the risk of perforation and the risk of cardiac tamponade if perforation occurs. When viewed on a chest radiograph, the catheter tip should be above the level of the carina, which ensures

**BOX 1 INDICATIONS FOR CENTRAL VENOUS CATHETERISATION**

- **Access for drugs**
  - Infusion of irritant drugs—for example, chemotherapy
  - Total parenteral nutrition
  - Poor peripheral access
  - Long term administration of drugs, such as antibiotics
- **Access for extracorporeal blood circuits**
  - Renal replacement therapy
  - Plasma exchange
- **Monitoring or interventions**
  - Central venous pressure
  - Central venous blood oxygen saturation
  - Pulmonary artery pressure
  - Temporary transvenous pacing
  - Targeted temperature management
  - Repeated blood sampling

**BOX 2 POTENTIAL CONTRAINDICATIONS TO CENTRAL VENOUS CATHETERISATION**

- Coagulopathy
- Thrombocytopenia
- Ipsilateral haemothorax or pneumothorax
- Vessel thrombosis, stenosis, or disruption
- Infection overlying insertion site
- Ipsilateral indwelling central vascular devices

CVC-BSI=central venous catheter bloodstream infections.

What are the complications of central venous catheterisation?

Complications are divided into immediate and delayed, then subdivided into mechanical, embolic, and infectious (table 2). Strict attention to insertion technique and correct line-tip positioning reduces the risks of many of the mechanical and embolic complications of catheter insertion. Complications such as air embolism may occur at any point during the lifetime of the line and can be related to poor technique during line insertion, use of the line, or line removal.

Infective complications

The mean central venous catheter bloodstream infection (CVC-BSI) rate documented in a large study of 215 UK intensive care units (ICUs) that submitted data for up to 20 months was 2.0 per 1000 central venous catheter days. In a 2011 UK national point prevalence survey on healthcare associated infections and antimicrobial use, 40% of primary blood stream infections were related to a central venous catheter. An American case-control study of critically ill patients found that nosocomial bloodstream infection was associated with increased mortality, length of stay in hospital and intensive care, and economic burden.

What are the clinical signs of line infection?

Clinical signs are unreliable. Fever is the most sensitive clinical finding but is not specific. The presence of inflammation or pus at the catheter exit site is more specific but less sensitive. Consider a diagnosis of CVC-BSI in patients with signs of systemic infection in the absence of another identifiable source or who develop signs of systemic infection after flushing of the line. Box 4 details the laboratory diagnosis of this infection. Maintain a high index of suspicion when blood cultures are positive for Staphylococcus aureus, coagulase negative staphylococci, or candida with no other obvious source for bacteraemia.

What are the common causes of central venous catheter infection or colonisation?

Colonisation occurs on the endoluminal or extraluminal surface of the line. Extraluminal colonisation occurs early after line insertion—micro-organisms from the skin colonise the line during insertion or migrate along the catheter tract. Less often, extraluminal colonisation occurs by haematogenous seeding of infection from a distant site. Endoluminal contamination occurs late and is caused by manipulation of the catheter hubs during interventions or more rarely from contamination of infusate. The organisms causing catheter colonisation and infection are most commonly coagulase negative staphylococci (particularly Staphylococcus epidermidis), enterococci, S aureus, and Candida spp.

It is not always possible to prove that the central line is the source of infection. For the purposes of research and epidemiological surveillance, two terms are used to describe CVC-BSI (box 4): catheter related bloodstream infection and central line associated bloodstream infection.

Establishing the criteria for catheter related bloodstream infection requires specialist microbiological testing or line removal (box 4). It is often not possible to remove the catheter or gain access to quantitative blood cultures. Unlike catheter related bloodstream infection, central line associated bloodstream infection does not require direct microbiological evidence of line contamination to identify the catheter as the cause, so this diagnosis often overestimates the rate of catheter infection.

Do antimicrobial or antiseptic impregnated catheters reduce the rate of CVC-BSI?

Impregnating the surface of the catheter with antiseptic or antimicrobial substances (such as chlorhexidine and silver sulfadiazine) reduces CVC-BSI. A Cochrane review of the effectiveness of this approach for reducing CVC-BSI in adults included 56 studies and 16,512 catheters with 11 different types of impregnation, bonding, or coating. Catheter impregnation reduced the risk of catheter related bloodstream infections and catheter colonisation. The rate of sepsis or all cause mortality was not reduced, and the benefit of impregnation varied with the clinical setting, being most beneficial in the ICU. The draft epic 3 guidelines recommend that impregnated lines should be used only in patients who are expected to have a catheter in place for more than five days and in units where the CVC-BSI rate remains high despite implementation of a package to reduce it.

Do multi-lumen central venous catheters increase the risk of infection?

A meta-analysis of all the available evidence concluded that multi-lumen catheters may be associated with a slightly higher risk of infection than single lumen ones. However, when only high quality studies (which controlled for patient differences) were considered, there was no increase in infection risk. Therefore, insert a catheter with the minimum number of lumens considered essential for patient care.

Does antibiotic prophylaxis reduce infection rates?

A Cochrane review concluded that prophylactic vancomycin or teicoplanin given before insertion of a tunnelled catheter in patients with cancer did not significantly reduce the number of early Gram positive line infections. A review of 16 randomised controlled trials found insufficient evidence to recommend the routine use of antibiotic lock solutions for preventing CVC-BSI.
Do not use prophylactic antibiotics before line insertion, antibiotic lock solutions, or antibiotic ointments applied to the insertion site. These strategies do not reduce rates of CVC-BSI and, theoretically, routine use could alter patterns of antimicrobial resistance.

**What interventions will reduce infective complications?**

There is no evidence that the type of dressing placed over the insertion site influences the rate of catheter related infection. A Cochrane review of two small studies found no difference between gauze and tape versus transparent polyurethane dressings.\(^\text{26}\) The draft epic 3 national evidence based guidelines for preventing healthcare associated infections recommend use of a transparent semipermeable polyurethane dressing.\(^\text{24}\) If there is bleeding or excessive moisture, a sterile gauze dressing can be used initially and replaced with a transparent dressing when possible. The dressing is not changed unless it is dislodged or there is pooling of fluid or blood under the dressing.

Intraluminal contamination of the catheter occurs through its access sites, so more frequent access through the catheter hub increases the likelihood of microbial contamination. Decontaminate the catheter hub or access port with 2% chlorhexidine in 70% alcohol before and after access.

The catheter can be exchanged over a guide wire or inserted at a different site. Evidence does not support the routine exchange of central venous catheters. A systematic review of exchange techniques showed that guide wire exchange was associated with a reduction in mechanical complications but also an increase in the frequency of catheter colonisation and CVC-BSI; however, none of these associations were significant.\(^\text{19}\) Four trials comparing prophylactic catheter exchange at three days versus exchange at seven days, or as needed, found no differences in rates of catheter colonisation or CVC-BSI. Do not guide wire exchange a new catheter through a line that is known to be infected; however, if the risk of mechanical complications related to line insertion is high, and the current catheter is not infected, guide wire replacement is reasonable.

A meta-analysis has shown that daily bathing of ICU patients with chlorhexidine gluconate reduces healthcare related infection and central line associated bloodstream infection,\(^\text{20}\) but in our experience this is not common practice in the UK.

The duration that a line should remain in situ before elective exchange or removal is not known. Review the ongoing requirement for a central line daily. Consider removal if it is no longer essential, the catheter is non-functioning, or there is associated infection or thrombosis. The decision to remove the line is made in the context of its clinical indication, the difficulty of establishing further central venous access, and the risk of it remaining in situ.

**System based strategies to reduce rates of CVC-BSI**

In a collaborative cohort study, implementation of a bundle of evidence based interventions significantly reduced CVC-BSI in 103 ICUs in Michigan, US; the benefit persisted for 18 months.\(^\text{17}\) The interventions comprised:

- Hand washing
- Using full barrier precautions during insertion
- Cleaning the skin with chlorhexidine
- Avoiding the femoral site if possible
- Removing unnecessary catheters.

The ICU staff also implemented a daily goals sheet to improve communication between clinicians, an intervention to reduce the incidence of ventilator associated pneumonia, and a comprehensive safety programme to improve the safety culture. The reduction in CVC-BSI was maintained 36 months after implementation of the interventions.\(^\text{17}\) Using a similar approach, in the UK, a two year stepped intervention programme (Matching Michigan) was associated with a marked reduction in rates of CVC-BSI in 196 adult ICUs (mean 3.7 CVC-BSIs/1000 catheter patient days in the first cluster to mean 1.48 CVC-BSIs/1000 catheter patient days for all clusters combined; P<0.0001).\(^\text{19}\)

What are the risks and complications of central venous catheter related thrombosis?

The presence of a central venous catheter is an independent risk factor for venous thromboembolism,\(^\text{39}\) but many of the indications for placement of a catheter are also risk factors for the development of thromboembolism (box 5).

Catheter related thrombosis can be symptomatic or asymptomatic. The thrombus is present on the catheter itself or on the vessel wall. Symptomatic thrombosis is diagnosed with duplex ultrasonography or contrast venography. It is associated with symptoms and signs such as swelling of the affected limb, discomfort, erythema, low grade fever, and dilation of collateral veins. Asymptomatic thrombosis is diagnosed on screening or coincidental imaging in the absence of associated signs or symptoms. Asymptomatic thrombosis may present with line occlusion. Reported rates of catheter related thrombosis vary widely—from 2% to 67%; the incidence of symptomatic catheter related thrombosis is 0–28%.\(^\text{34}\)

---

**BOX 4 CRITERIA FOR THE DIAGNOSIS OF CENTRAL VENOUS CATHETER RELATED INFECTIONS (CENTERS FOR DISEASE CONTROL AND PREVENTION (CDC) DEFINITIONS)**

**Catheter related bloodstream infection***

- Presence of an intravascular device
- Evidence of systemic infection—pyrexia, tachycardia, or hypotension in the absence of another source of infection
- Laboratory evidence that the catheter is the source:
  - If the catheter has been removed: quantitative or semiquantitative culture of the catheter
  - If the catheter remains in situ: quantitative paired blood cultures (peripheral cultures and cultures drawn from central catheter) or differential time to positivity of paired blood cultures

**Central line associated bloodstream infection***

- Evidence of systemic infection
- Central line has been in situ during the 48 hours before blood being cultured
- Laboratory confirmed bloodstream infection on peripheral blood culture
- No evidence of infection from another site

*All criteria needed for a diagnosis.

---

**BOX 5 RISK FACTORS FOR CENTRAL VENOUS CATHETER RELATED THROMBOSIS**

**Patient related factors**

- Hypercoagulable state (acute or chronic)
- Cancer
- Cancer treatment
- Age
- Previous deep vein thrombosis

**Device related factors**

- Line material
- Number of lumens (catheter diameter)
- Previous deep vein thrombosis
- Position of catheter tip
- Presence of line infection
- Line insertion site
Potential complications of catheter related thrombosis are thromboembolism, interruption of venous flow, line infection, and catheter occlusion. The thrombus may embolise to the right heart or pulmonary circulation. The reported incidence of symptomatic pulmonary embolism is 0-17% in patients with catheter related thrombosis. The thrombus may act as a site for bacterial growth.

The post-thrombotic syndrome is well described in deep vein thrombosis unrelated to central venous catheterisation and is characterised by venous hypertension, swelling, and pain. There is little evidence to establish the risk of the post-thrombotic syndrome and recurrent thrombosis after catheter related thrombosis.

**How can catheter related thrombosis be prevented?**

The use of prophylactic anticoagulants to prevent catheter related thrombosis has been studied extensively. A Cochrane review of anticoagulation in patients with cancer and a central venous catheter found no significant effect of low dose vitamin K antagonists or low dose unfractionated heparin on mortality, infection, bleeding, or thrombocytopenia.

A meta-analysis of 15 studies (10 of patients with cancer and five of patients receiving long term parenteral nutrition) found that anticoagulant prophylaxis reduced the risk of all catheter related thromboses (symptomatic and asymptomatic) but not the rate of pulmonary embolism or mortality.

On the basis of these data, use of anticoagulant prophylaxis to prevent catheter related thrombosis is not recommended.

**How should I treat catheter related thrombosis?**

Treatment of catheter related thrombosis includes prevention of complications and management of the central venous catheter. Therapeutic anticoagulation reduces the risk of embolic complications and of the post-thrombotic syndrome, and it prevents recurrent thrombosis. Consider anticoagulation in any patient with a demonstrable deep vein thrombosis on imaging. International evidence based guidelines recommend that patients with cancer and symptomatic catheter related thrombosis are given anticoagulants for three months—low molecular weight heparin or vitamin K antagonists. Thrombolytic treatment has the potential to restore venous patency and catheter patency. Although a Cochrane review found inadequate evidence to support or refute the use of thrombolysis to restore catheter patency, this strategy is commonly used. If the catheter is positioned correctly, functioning, and not infected, it may be left in situ. Remove the catheter if distal limb swelling is not resolving.

Peripheral inserted central catheters

Peripheral inserted central catheters (Fig 1C) provide intravenous access for long term antibiotics—particularly for patients with difficult intravenous access and for those receiving intravenous antibiotics in the community—and for parenteral nutrition, chemotherapy, blood products, and blood sampling. They can be left in situ for several months. Their recent popularity probably reflects improved access to this technique delivered at the bedside by dedicated vascular access teams, as well as a belief that these lines combine the advantages of central access with a reduction in the risks associated with traditional central venous catheters. Although these lines are associated with fewer mechanical complications at insertion, a recent systematic review and meta-analysis of 64 studies found that the rates of upper extremity deep vein thrombosis are higher with peripherally inserted central catheters than with central venous catheters. This increase in risk is greatest in critically ill patients and those with cancer.

Two further reviews comparing complication rates with these two types of catheter have challenged the established belief that peripheral lines are safer. The authors of one review concluded that malpositioning of the catheter tip, thrombophlebitis, and catheter dysfunction were more common with these lines than with central venous catheters, and the authors of both reviews conclude that there is no difference in rates of infection associated with either line in hospital inpatients.

Although often considered a safe and convenient solution to difficult intravenous access in the long term, the risks and benefits of peripherally inserted lines must be considered carefully before insertion.

**Caring for central venous catheters**

Responsibility for the daily care of long term central lines is often delegated to patients and their relatives or carers. Meticulous attention to detail in care will reduce the likelihood of a line related complication. The sterile, transparent, semipermeable dressing is removed weekly, or sooner if it is soiled or not intact. Before replacing the dressing, clean the insertion site with 2% chlorhexidine in 70% alcohol. If the line is not used regularly, aspirate and flush all lumens weekly. To reduce the risk of line infection, patients are advised to shower and not bathe (if bathing, do not submerge the line in water). Swimming is not recommended because the line will be completely submerged. Vigorous physical activity involving the upper body may cause the line to be displaced and should be avoided. Patients with long term central venous catheters with implanted ports are free from all of these restrictions.

Management of paracetamol poisoning

Robin E Ferner, honorary professor of clinical pharmacology12, James W Dear, consultant clinical pharmacologist34, D Nicholas Bateman, professor of clinical toxicology3

Paracetamol (acetaminophen) is an effective oral analgesic, with few adverse effects when used at the recommended dose. Nevertheless, paracetamol poisoning is common and potentially fatal. It is a leading cause of acute liver failure in the United Kingdom1 and the United States.2 Potential liver damage, predicted from blood paracetamol concentration and time from ingestion, can be prevented by prompt treatment with antidote. However, young and otherwise healthy patients still risk serious liver injury, especially if they present more than a few hours after overdose or take staggered overdoses over hours or days.4

How does paracetamol cause damage and who is at risk?
The recommended therapeutic dosage of paracetamol depends on age (table 1). Therapeutic doses of paracetamol are mainly metabolised by conjugation to inactive metabolites. Paracetamol predominantly damages the liver.4 The reactive metabolite, N-acetyl-p-benzoquinoneimine (NAPQI), formed when paracetamol is oxidised by the cytochrome P450 enzyme family, is the key to hepatic injury. NAPQI binds covalently to sulphydryl groups, which can be provided by glutathione; but when glutathione stores are depleted NAPQI binds to cellular proteins (fig 1). Toxicity is therefore affected by the rate of enzyme catalysed formation of NAPQI, which can be induced by several drugs and chronic alcoholism, and by the availability of glutathione, which depends crucially on nutritional status. Thus, some patients are more susceptible than others to liver injury from paracetamol ingestion—box 1 lists the risk factors. After covalent binding of NAPQI to cellular proteins, cell injury is mediated by free radicals. An inflammatory response follows cell death and may determine the outcome once liver injury is established.7

SUMMARY POINTS

1 Patients still die from paracetamol poisoning because they are not recognised to be at risk of harm or present too late for effective treatment
2 Patients who are malnourished, have been fasting, take enzyme inducing drugs, or regularly drink alcohol to excess are at higher risk of liver damage
3 Treat patients who have ingested too much paracetamol within eight hours of ingestion whenever possible
4 If the time of ingestion is known, treatment can be based on blood tests taken after four hours
5 If the timing is uncertain or unknown, treatment should be started immediately in all patients who are at potential risk
6 Treat patients as high risk unless factors that increase risk of harm are known to be absent

Sources and selection criteria
We based our review on a PubMed search for articles on paracetamol (or acetaminophen) and acetylcysteine or (N-acetylcysteine) published between 1 January 1990 and 31 December 2010, without language limits. The search was limited to human clinical trials, meta-analyses, randomised controlled trials, reviews, and case reports. We also searched a newspaper database for reports published after 1988 of coroners’ inquests and procurators’ fiscal inquiries into fatal cases of paracetamol poisoning. In addition, we used a bibliography and our own collections of relevant references.3

How does paracetamol cause damage and who is at risk?

Paracetamol (acetaminophen) is an effective oral analgesic, with few adverse effects when used at the recommended dose. Nevertheless, paracetamol poisoning is common and potentially fatal. It is a leading cause of acute liver failure in the United Kingdom1 and the United States. Potential liver damage, predicted from blood paracetamol concentration and time from ingestion, can be prevented by prompt treatment with antidote. However, young and otherwise healthy patients still risk serious liver injury, especially if they present more than a few hours after overdose or take staggered overdoses over hours or days.4

How do patients with paracetamol overdose present?
Many patients who present do so within a few hours of taking an overdose, when symptoms and signs are absent or confined to nausea and vomiting. Lactic acidosis and coma can, exceptionally, occur soon after ingestion of massive amounts of paracetamol. Their presence usually implies mixed overdose. Right upper quadrant tenderness is common in patients presenting with established liver damage. Patients who present after 24 hours may already have signs of liver failure—hepatic tenderness, jaundice, impaired consciousness, asterixis, foetor hepaticus, and haemorrhage. Overt liver failure can, however, be delayed for two or three days. It is important not to overlook paracetamol in those who have signs suggesting overdose with another agent.

How should the patient with suspected paracetamol poisoning be investigated?
The history is crucial in patients who do not yet have liver failure because it determines the risk of serious liver damage, and hence treatment strategy. Ascertain the dose and timing of ingestion, and whether a patient may be more susceptible than average to the toxic effects of paracetamol (box 1).

Dose of paracetamol
After a single overdose, the patient may be able to say how many tablets have been taken. Difficulties arise if the tablets have been taken over a period, or if the patient is unable or unwilling to give the relevant information.

Time of ingestion
Knowing the time of tablet ingestion is crucial for calculating whether treatment with antidote is needed. Because it takes some time to swallow a substantial number of tablets, take the start of ingestion as the relevant time if all tablets were taken during a period shorter than one hour, otherwise treat as a staggered overdose. In cases of staggered overdose, more than one supratherapeutic dose, or if the patient has been poisoned with an intravenous or modified release formulation,21 decisions regarding treatment are more difficult.

Physical examination
As well as eliciting signs of liver damage from paracetamol, the examination may indicate that the patient is more susceptible to developing such damage (see box 1)—for example, because the patient is malnourished.3 It may also identify an antecedent liver disorder.
Investigation
The crucial investigations are the timed serum paracetamol concentration, to determine risk of liver damage, and tests of liver function (including prothrombin time or international normalised ratio) and kidney function. These tests are needed to assess risk and monitor progress. Prognosis is worse if they are abnormal at presentation. Paracetamol concentration in venous blood should be measured between four and 16 hours after ingestion of a single dose to allow the patient’s risk to be determined from the standard nomograms (discussed below). Values obtained earlier than four hours cannot be interpreted because absorption is not yet complete. Values taken after 16 hours may be high because of acute liver injury that delays paracetamol metabolism, or falsely reassuring, even though irreversible liver damage has already occurred. In untreated patients with negative tests for paracetamol and normal hepatic and renal function 24 hours after exposure, serious harm is unlikely.

†A ceiling weight of 110 kg is recommended when calculating the dosage for obese patients.

*Acetylcysteine in glucose 5% solution.

Ketones on urinalysis and low blood urea concentration can indicate starvation or poor nutrition, which increases the risk of liver damage. Raised γ-glutamyl transpeptidase activity is a potentially useful indicator of hepatic enzyme induction.

What is the initial approach to treatment?
Out of hospital treatment
Treatment depends on adequate assessment, first aid measures, and transfer of at risk patients for antidotal treatment. Activated charcoal taken soon after overdose should reduce absorption of paracetamol. It is unlikely to help more than an hour after overdose.

Acetylcysteine
The mainstay of treatment for patients who have taken a potentially toxic dose of paracetamol is the antidote acetylcysteine, which is a sulphydryl donor. It is given intravenously in three sequential infusions, each containing a different dose of antidote, and is based on the patient’s body weight (up to a maximum dose equivalent to a weight of 110 kg) (table 2).

At therapeutic doses
Oxidation by cytochrome P450 enzymes is a minor route
Paracetamol
Conjugation is the major route of metabolism
NAPQI

Reacts with SH– group in glutathione
Paracetamol conjugate

In overdose
Oxidation by cytochrome P450 enzymes becomes important
Paracetamol
Excess NAPQI binds to SH– groups in cellular protein
NAPQI conjugate

Binds to cellular proteins and causes cell injury
Paracetamol conjugate

Glutathione supply exhausted
NAPQI conjugate

Fig 1 At therapeutic doses, paracetamol is mainly metabolised by conjugation to inactive metabolites. A reactive metabolite, N-acetyl-p-benzoquinoneimine (NAPQI), is formed by oxidation. When a large dose of paracetamol is taken, more NAPQI is formed, sulphation conjugation pathways are saturated, and NAPQI binds covalently to sulphydryl (SH–) groups. These can be provided by glutathione, but when hepatic glutathione stores are depleted, NAPQI binds to cellular proteins and causes cell injury

Fig 2 The graph shows how a relatively small inaccuracy in timing could result in the wrong course of action. Paracetamol concentration is shown on the y axes (as both mg/L (left hand axis) and mmol/L (right hand axis)) and time from overdose on the x axis for patients at high risk (lower line) and normal risk (upper line). In this example, the sample is thought to have been taken at four hours (1) after overdose, in which case no treatment would be needed (in a patient at normal risk). If, however, the wrong time had been given and the sample had actually been taken at five hours (2) after overdose—and more clearly if had been taken at eight hours (3)—it would require treatment

*Acetylcysteine in glucose 5% solution.
†A ceiling weight of 110 kg is recommended when calculating the dosage for obese patients.
Acetylcysteine replenishes glutathione stores, which at least partly explains its antidotal efficacy. A large multicentre study of efficacy published in 1988 found that the antidote is uniformly effective if given within eight hours of a single overdose, but subsequently its efficacy falls. A controlled trial provided evidence that acetylcysteine can improve outcome even in patients with encephalopathy, so those who present more than eight hours after overdose are still treated with the antidote if they are deemed at risk of liver damage or if liver function is already abnormal.

A retrospective cohort study of more than 4000 patients showed that intravenous treatment is at least as effective as oral treatment but takes less time to administer. Intravenous treatment can be administered reliably even if the patient is vomiting.

Findings from animal studies suggest that the alternative sulphhydryl donor methionine is less effective than acetylcysteine.

The treatment nomogram

Decisions to treat paracetamol overdose with acetylcysteine are based on an assessment of the risk of serious liver damage. The treatment nomogram, originally derived from a study of just 32 patients, separates those who will develop serious hepatotoxicity (transaminase activity >1000 U/L) from those who will not on the basis of a graph of paracetamol concentration against time from ingestion as it falls from 200 mg/L at four hours (the “200” line) (fig 2). Healthcare professionals can consult their poisons information service (in the UK and Ireland: www.toxbase.org/) for treatment recommendations.

In the US, Australia, and New Zealand a similar semi-logarithmic plot at paracetamol concentrations 25% lower (the “150” line) is used to permit a wider margin of error. Some patients reportedly come to harm even if the paracetamol concentration falls below the 200 or 150 lines. An appreciation of the factors that increased the risk of liver damage led to the introduction in the UK of a second (high risk) line, running laterally through the nomogram (fig 2). We strongly advise that all patients be treated according to the high risk line unless factors that increase the risk of harm (box 1) are known to be absent.

**BOX 1 FACTORS THAT INCREASE THE RISK OF LIVER INJURY AFTER AN OVERDOSE OF PARACETAMOL**

- High chance of glutathione depletion:
- Malnourished (for example, not eating because of dental pain or fasting for more than a day)
- Eating disorders (anorexia or bulimia)
- Failure to thrive or cystic fibrosis in children
- AIDS
- Cachexia
- Alcoholism
- Clinical clues: history, low body mass index, urinalysis positive for ketones, low serum urea concentration
- Hepatic enzyme induction:
- Long term treatment with enzyme inducing drugs, such as carbamazepine, phenobarbital, phenytoin, primidone, rifampicin, rifabutin, efavirenz, nevirapine, and St John’s wort
- Regular consumption of ethanol in excess of recommended amounts
- Clinical clues: history, abnormal liver function tests, increased international normalised ratio, increased γ-glutamyl transpeptidase
- Abnormal renal or hepatic function at presentation

**Fig 3** A wide range of branded products on open sale, many of which contain paracetamol. Mistakes can be made when estimating the risk of hepatic damage after paracetamol overdose. Whenever risk assessment is difficult or uncertain, we recommend that the patient is taken to be at high risk.

**BOX 2 CRITERIA FOR POSSIBLE LIVER TRANSPLANTATION**

<table>
<thead>
<tr>
<th><strong>CRITERIA</strong></th>
</tr>
</thead>
<tbody>
<tr>
<td>Arterial pH less than 7.3</td>
</tr>
<tr>
<td>Hepatic encephalopathy grade III or IV and serum creatinine concentration &gt;300 μmol/L and prothrombin time &gt;100 seconds</td>
</tr>
<tr>
<td>Arterial lactate concentration &gt;3.5 mmol/L on admission or &gt;3.0 mol/L 24 hours after paracetamol ingestion or after fluid resuscitation</td>
</tr>
</tbody>
</table>

It is best to discuss transplantation with a liver transplant unit as soon as the possible need is identified.

**BOX 3 CASE SCENARIO 1**

A 19 year old woman with a rare syndrome, which meant she weighed just five and a half stone (35 kg) and was only four feet tall, was admitted to a neurology ward. She was prescribed intravenous paracetamol 1 g, when the correct (weight adjusted) dose was 535 mg. She received a total of 20 doses. When she developed fatal liver failure as a result, this was initially ascribed to Reye’s syndrome. (Evening Times (Glasgow) 2010 September 17; [http://news.stv.tv/scotland/west-central/186253-doctor-tells-court-of-battle-to-save-danielle-welsh/](http://news.stv.tv/scotland/west-central/186253-doctor-tells-court-of-battle-to-save-danielle-welsh/))

**BOX 4 CASE SCENARIES 2 AND 3**

A 72 year old woman died after taking capsules of Lemsip Max cold relief as well as her prescribed paracetamol. She was taking the daily dose of paracetamol for pain and had been mixing it with the Lemsip Max for about a week—almost doubling her normal dose. After the court hearing, her husband urged people to read the labels carefully and called for large warnings about the dangers of paracetamol overdose to be printed on the front of packets. “(My wife) knew too much paracetamol was dangerous but she did not realise there was paracetamol in Lemsip. If you go into a chemist and ask for something the first thing they ask is if you are taking any medication. But if you go into a supermarket there is no proper dispensary counter and the people at the check-out don’t know anything about it.” (This is Bradford 2004 July 21.)

A 43 year old woman with a history of polymyositis was prescribed a paracetamol based painkiller known as Kapake by her general practitioner for a dental abscess, but she was also taking standard paracetamol tablets. She was admitted to hospital with a suspected recurrence of the polymyositis, but tests showed she had serious liver damage, from which she later died. (This is Lancashire 2004 November 25.)
The risk assessment nomogram requires the time from ingestion to be known with reasonable accuracy (fig 2). The efficacy of the antidote declines from about eight hours after overdose, so it is important not to delay treatment of potentially poisoned patients beyond eight hours even if the paracetamol concentration is not known. The nomogram is misleading or unhelpful if the overdose was repeated or staggered, if the exact timing is unclear, or if the patient received an intravenous preparation, because the pharmacokinetics of such preparations are different. In these circumstances, the initial treatment decision has to be based on the total dose, taking any risk factors into account; subsequently, abnormalities in renal and hepatic function tests will guide treatment.

How to manage the patient after administering the antidote
Liver damage can be detected by measuring international normalised ratio, serum creatinine concentration, and liver function at the end of acetylcysteine treatment; some units also measure paracetamol concentration because appreciable concentrations can indicate a risk of continuing damage. UK guidelines, which have extrapolated from the study of acetylcysteine in encephalopathy, suggest that if the international normalised ratio exceeds 1.3, or transaminases have increased to more than double baseline values, then the antidote should continue to be infused at a dose of 100 mg/kg over 16 hours until results are acceptable. Patients with renal dysfunction after paracetamol poisoning require ongoing monitoring and may need renal support.

Why do patients still die from paracetamol poisoning?
Most deaths in the UK occur because patients present to hospital too late for the antidote to be effective. The diagnosis of paracetamol poisoning may be missed in patients who take a dose only slightly higher than therapeutic but have one or several factors that increase the risk of hepatotoxicity (box 3), when drug errors occur, and in patients who have inadvertently taken more than the recommended dose of paracetamol in two or more different preparations containing paracetamol (box 4, fig 3).

Paracetamol poisoning may also be missed in patients who have taken a mixed overdose and are unconscious, because unconsciousness is rare in paracetamol poisoning. Mistakes can be made when estimating the risk of hepatic damage after paracetamol overdose. Whenever risk assessment is difficult or uncertain, we recommend that the patient is assumed to be at high risk.

Treatment errors can occur when paracetamol concentrations are misunderstood. The cardinal measurement in ascertaining risk is the timed plasma paracetamol concentration. Patients have died when doctors have thought that results quoted in mmol/L are actually in mg/L (151 mg=1 mmol) and have therefore withheld acetylcysteine. The acetylcysteine regimen is complex, and errors are common. Errors also arise when absorption of paracetamol is delayed because co-ingestion of a drug such as codeine or an anticholinergic antihistamine has slowed gastric emptying and thus delayed absorption of paracetamol, or a modified release formulation has been taken. In such circumstances, toxic paracetamol concentrations may be reached much longer than four hours after overdose.

Patients also come to harm when non-immunological adverse reactions to acetylcysteine are interpreted as anaphylaxis and the antidote is withheld.

Areas of uncertainty
The optimal dosage of acetylcysteine and the appropriate dose adjustment for body weight remain unclear and are difficult to study in patients. Because the initial rapid infusion seems to cause most adverse effects, some people advocate giving the loading dose over one hour, although this is of no confirmed benefit. Better indicators of prognosis both at presentation and as a warning of impending liver failure, and more secure criteria for liver transplantation, are needed.

Drugs that prevent mitochondrial injury and drugs that target key inflammatory mediators have been shown to prevent injury from paracetamol in experimental models and represent potential new therapeutic targets.

Hyperkalaemia

Moffat J Nyirenda, MRC clinician scientist/honorary consultant physician1, Justin L Tang, research fellow1, Paul L Padfield, professor of hypertension2, Jonathan R Seckl, professor of molecular medicine1

Hyperkalaemia is defined as serum potassium concentration greater than 5.5 mmol/l. Its prevalence in the general population is unknown, but it is thought to occur in 1-10% of patients admitted to hospital.1 The rate of morbidity and mortality associated with hyperkalaemia has risen greatly with the use of drugs that target the renin-angiotensin system, and since publication 10 years ago of a randomised trial that showed that adding an aldosterone receptor antagonist to usual treatment for congestive failure improved outcomes.2 3 4 5

Potassium is the most abundant cation in the human body and has key roles in the excitatory properties needed for conduction of nerve impulses and muscle contraction. Ninety eight per cent of the body’s potassium is in the intracellular fluid (concentration about 140 mmol/l), with only 2% in extracellular fluid (3.8-5.0 mmol/l). A complex interplay of regulatory mechanisms is needed to maintain normal potassium balance, which involves the transfer of potassium between the extracellular and intracellular compartments (fig 1). In the long term potassium homoeostasis is mainly governed by regulation of renal potassium excretion, notably by the actions of aldosterone (fig 2). These mechanisms ensure that although total daily potassium intake could range from 40 mmol to 200 mmol per day, potassium levels in serum remain within the relatively narrow normal range. Derangements in potassium regulation, and resultant changes in serum potassium concentration, may alter membrane excitability. Disorders of plasma potassium can therefore have profound effects on nerve, muscle, and cardiac function.

What are the common causes of hyperkalaemia?
Multiple factors are often involved in the pathogenesis of hyperkalaemia, which commonly results from decreased potassium excretion or increased release of potassium from cells.6 Hyperkalaemia can be spurious, and this possibility should be excluded first, except in severe cases when immediate treatment is needed.

Spurious hyperkalaemia
Spurious hyperkalaemia (also called pseudohyperkalaemia) occurs when the reported laboratory potassium values do not reflect actual in vivo concentrations—usually because platelets, leucocytes, or erythrocytes have released intracellular potassium in vitro. It can be excluded by sending a new sample for analysis or by simultaneously measuring potassium in plasma and serum; serum potassium concentration is usually 0.2-0.4 mmol/l higher than that in plasma, owing to release during normal clotting. Box 1 lists common causes of spurious hyperkalaemia.

Hyperkalaemia due to increased potassium intake
Excessive dietary intake of potassium is an uncommon cause of hyperkalaemia, unless concurrent decreased excretion is a factor. High potassium intake should be avoided in patients with compromised renal function. Box 2 lists foods rich in potassium. Hyperkalaemia can also occur with blood transfusion (due to release of potassium from haemolysis), when intravenous potassium is administered too rapidly in treatment of hypokalaemia, or when total parenteral nutrition contains high concentrations of potassium.

Hyperkalaemia caused by shift of potassium out of cells
Several endogenous and exogenous factors can affect transfer of potassium between the extracellular and intracellular fluid to raise the concentration in serum. However, this mechanism is rarely the sole cause of severe hyperkalaemia, except when excessive release of intracellular potassium occurs with tissue injury or necrosis—for example, in rhabdomyolysis, tumour lysis, and severe burns. Box 3 shows causes of hyperkalaemia due to potassium redistribution.

Hyperkalaemia caused by reduced excretion of potassium
The kidneys are the main route of potassium elimination, and renal failure is the major cause of hyperkalaemia, accounting for up to 75% of cases of severe hyperkalaemia.7 In patients with chronic kidney disease, the capacity to excrete potassium is reasonably well maintained until renal failure is advanced (glomerular filtration rate <15-20 ml/min); until then hyperkalaemia is not usually seen unless intake of potassium is high or the patient is taking a drug that promotes hyperkalaemia.

Damage to the juxtaglomerular apparatus with resulting deficit in renin production can cause hyporeninaemic hypoaldosteronism, which can also cause hyperkalaemia in the absence of severe renal failure. Hyporeninaemic hypoaldosteronism is also known as type 4 renal tubular acidosis because it is often, but not always, associated with mild to moderate metabolic acidosis with a normal anion gap. Diabetic nephropathy is the most common underlying cause. Hypoaldosteronism can also be caused by primary disorders of the adrenal gland (such as Addison’s disease or congenital steroidogenic enzyme defects, most commonly 21 hydroxylase deficiency) or by reduced mineralocorticoid activity due to...
resistance to the action of aldosterone action in the kidney. The latter problem is often seen in sickle cell anaemia, systemic lupus erythematosus, amyloidosis, and obstructive nephropathy or with use of potassium sparing diuretics. In rare cases, it is caused by mutations of the gene encoding the mineralocorticoid receptor or its major downstream targets, including the epithelial sodium channel ENaC.

In general, an abnormality in mineralocorticoid level by itself does not produce hyperkalaemia if sufficient amount of sodium is delivered to the distal nephron. Thus, patients with Addison’s disease do not usually exhibit hyperkalaemia if they have adequate salt intake; it is only when sodium intake is restricted or they otherwise become volume depleted that hyperkalaemia develops. Disturbances of urinary flow rate or delivery of sodium to the distal nephron are therefore also important in the pathogenesis of hyperkalaemia. These defects can be intrinsic or (more commonly) caused by drugs (box 3, box 4).

Which drugs cause hyperkalaemia?

Drugs can interfere with potassium homeostasis by promoting transcellular potassium shift or by impairing renal potassium excretion (for example, through effects on aldosterone action, sodium delivery to the distal nephron, or function of collecting tubules).\(^1\) In a prospective study of 242 consecutive patients admitted with hyperkalaemia, 63% were taking drugs that interfere with potassium balance.\(^1\) The risk of hyperkalaemia is particularly great when such drugs are given to patients with underlying renal insufficiency. The elderly and patients with diabetes are especially susceptible.

Doctors should therefore prescribe such drugs with caution in these populations; it is best to start with low doses and to recheck serum potassium within a week of starting the drug, and with each increase in dose. There are no consensus guidelines as to what constitutes timely follow-up, but the frequency with which serum potassium is monitored will depend on the level of renal impairment, the presence of diabetes, and concurrent use of other hyperkalaemia inducing medications. Particular caution should be exercised in patients with underlying cardiac conduction defects, in whom even minor increases in serum potassium can precipitate severe arrhythmias. A comprehensive list of drugs associated with hyperkalaemia is given in box 4. We will briefly discuss some of the most commonly prescribed ones.

Angiotensin converting enzyme (ACE) inhibitors and angiotensin II receptor blockers (ARBs) are increasingly used for renoprotection and to reduce cardiovascular mortality in patients at high risk, particularly those with diabetes. They also are standard treatment in the management of patients with chronic heart failure. ACE inhibitors and ARBs predispose to hyperkalaemia because they impair aldosterone secretion and reduce renal perfusion (and thus glomerular filtration rate), both of which decrease excretion

**BOX 1 CAUSES OF SPURIOUS HYPERKALAEMIA**

- Laboratory error
- Delayed analysis
- Blood collected from vein into which potassium is infused
- Excessive tourniquet or repeated fist clenching
- Haemolysis via small needle or traumatic venepuncture
- Prolonged storage of blood
- Severe leucocytosis or thrombocytosis
- Uncommon genetic disorders (familial pseudohyperkalaemia)

**BOX 2 FOODS WITH HIGH POTASSIUM CONTENT**

- Salt substitutes
- Figs
- Molasses
- Seaweed
- Chocolates
- Bran cereal, wheat germ
- Vegetables (such as spinach, tomatoes, mushrooms, carrots, potatoes, broccoli, Lima beans, cauliflower)
- Dried fruit, nuts, and seeds
- Fruits (such as banana, kiwi fruit, orange, mango, cantaloupe)

Adapted from the National Kidney Foundation website (www.kidney.org/news/newsroom/fs_new/potassiumCKD.cfm)
of potassium by the kidneys. However, in general, they do not cause hyperkalaemia in patients with normal renal function; indeed, the degree of aldosterone suppression is usually not sufficient to substantially impair potassium excretion unless pre-existing hypoaldosteronism from other causes (disease state or from other drugs) is present. Unfortunately, most patients targeted for renovascular benefits of these drugs (such as those with diabetes, renal failure, or heart failure) are at high risk of developing hyperkalaemia. About 10% of outpatients develop hyperkalaemia within a year of starting treatment with ACE inhibitors or ARBs. Moreover, these drugs contribute to hyperkalaemia in 10–38% of patients admitted to hospital with the condition, with the risk increasing substantially when higher doses are used or when they are used in combination or with other hyperkalaemia inducing drugs.

Aldosterone (mineralocorticoid) receptor antagonists are also commonly prescribed to treat patients with congestive cardiac failure since the Randomized Aldactone Evaluation Study showed that the addition of spironolactone to standard treatment is associated with significant reduction in morbidity and mortality. Serious hyperkalaemia occurred in only 2% of patients in the study, where the average serum creatinine concentration was 106 µmol/l and the dose of spironolactone did not exceed 25 mg daily. By contrast, population based time-series analyses have demonstrated significant increases in rates of hospitalisation and mortality from hyperkalaemia. This is probably because these studies included patients with more severe renal dysfunction who were given higher doses of spironolactone. These patients were also more likely than those in the clinical trial to be taking potassium supplements or other drugs that impair potassium excretion. The risk was highest in patients who took spironolactone in combination with ACE inhibitors or ARBs, particularly in elderly patients with renal failure. Non-steroidal anti-inflammatory drugs (NSAIDs) inhibit renin secretion (leading to hypoaldosteronism and reduced potassium excretion) and can impair renal function. These agents should be prescribed judiciously in patients with diabetes or renal insufficiency, particularly if they are concurrently receiving ACE inhibitors or ARBs.

Aldosterone blocking drugs (see box 4)

End organ unresponsiveness to aldosterone (sickle cell anaemia, systemic lupus erythematosus, amyloidosis, and obstructive nephropathy)

Drugs that inhibit activity of epithelial sodium channel

Potassium sparing diuretics (amiloride, triamterene)

Trimethoprim

Pentamidine

How is hyperkalaemia diagnosed?

Hyperkalaemia is often asymptomatic and discovered on routine laboratory tests. When symptoms are present, they are non-specific and predominantly related to muscular function (paresthesiae, muscle weakness, fatigue) or cardiac function (palpitations). Hyperkalaemia may produce progressive abnormalities on the electrocardiogram (ECG), including peaked T waves, flattening or absence of P waves, widening of QRS complexes, and sine waves (fig 3). However, electrocardiography is not a sensitive method for detecting hyperkalaemia. In a study by Acer and colleagues nearly half the patients with serum potassium concentration greater than 6.5 mmol/l did not have ECG changes. Moreover, whereas some patients show gradual progression in changes, others progress from benign to potentially fatal ventricular arrhythmias without warning.

Assessment of a patient with hyperkalaemia should include a thorough review of the medical history to identify potential contributing factors such as renal failure, diabetes, adrenal insufficiency, and use of drugs that cause hyperkalaemia. Laboratory blood tests should be directed towards causes suggested by the history and physical examination, and should include urea, creatinine, electrolytes, and serum osmolality (acute increase in osmolality can cause potassium to exit from cells). Analysis of urine potassium concentrations could help to ascertain whether renal potassium elimination is appropriate. In selected patients, additional specialised tests such as measurement of the fractional excretion of potassium or transtubular potassium gradient may be useful in distinguishing between renal and non-renal causes of hyperkalaemia.

Assessment of a patient with hyperkalaemia should include a thorough review of the medical history to identify potential contributing factors such as renal failure, diabetes, adrenal insufficiency, and use of drugs that cause hyperkalaemia. Laboratory blood tests should be directed towards causes suggested by the history and physical examination, and should include urea, creatinine, electrolytes, and serum osmolality (acute increase in osmolality can cause potassium to exit from cells). Analysis of urine potassium concentrations could help to ascertain whether renal potassium elimination is appropriate. In selected patients, additional specialised tests such as measurement of the fractional excretion of potassium or transtubular potassium gradient may be useful in distinguishing between renal and non-renal causes of hyperkalaemia.
How is severe hyperkalaemia managed?

Guidelines for treatment of hyperkalaemia are based on consensus or expert opinion because of a lack of controlled clinical trials. Treatment should be aimed at restoring normal potassium balance, preventing serious complications, and treating the underlying causes. Figure 4 shows a general approach in management of patients with hyperkalaemia.

Mild to moderate hyperkalaemia can be treated with a loop diuretic to increase urinary potassium excretion. Dietary potassium is restricted and hyperkalemnic drugs should be minimised or withdrawn. If a patient has renal failure a diuretic may not be effective and other measures, including dialysis, may be needed.

Severe hyperkalaemia is a life threatening state because it can cause catastrophic cardiac and neuromuscular effects, such as cardiac arrest and paralysis of the respiratory muscles. Therefore prompt and aggressive treatment is necessary. Most authorities consider that serum potassium concentration of greater than 6.0 mmol/l with ECG changes, or greater than 6.5 mmol/l regardless of the ECG, represents severe hyperkalaemia that warrants urgent treatment. If the patient's ECG suggests hyperkalaemia, or in a clinical scenario such as cardiac arrest in a patient having chronic dialysis, for example, therapy is frequently started without waiting for laboratory confirmation. Other factors that might necessitate pre-emptive treatment of hyperkalaemia include a rapid rise of serum potassium, the presence of significant acidosis, and rapid deterioration in renal function.

Most guidelines and experts advise that severe hyperkalaemia should be treated in an inpatient setting to allow continuous cardiac monitoring, because even patients without symptoms or ECG changes can swiftly develop life threatening arrhythmias. Although urgent dialysis to remove potassium from the body would be the definitive treatment, delays in starting this treatment are inevitable. A 2005 Cochrane systematic review of emergency interventions for hyperkalaemia recommended that immediate temporising treatment incorporates three key measures.

The first step is to stabilise the myocardium to reduce its susceptibility to ventricular arrhythmias. Intravenous calcium is used to directly antagonise the membrane effects of hyperkalaemia, stabilising cardiac conduction. Calcium gluconate in a volume of 10 ml of 10% solution is infused over 3–5 minutes with cardiac monitoring. Calcium infusion does not affect serum potassium level, but beneficial ECG changes can be seen after 1-3 minutes of administration and the effect can last for 30-60 minutes. The infusion can be repeated if no effect is seen within 5-10 minutes. Caution should be exercised when replacing calcium in patients taking digoxin because calcium potentiates myocardial toxicity to digoxin.

The second step is to shift potassium from the extracellular to the intracellular fluid compartment so as to rapidly decrease serum potassium. This shift is achieved by administration of insulin or β2 agonist, both of which stimulate the Na+/K+ pump. Insulin is given as an intravenous bolus along with sufficient glucose to prevent development of hypoglycaemia (usually 10 units of insulin with 50 ml of 50% dextrose given over 5 minutes). The hypokalaemic effect of this treatment can be seen within 30 minutes, peaking between 30 and 60 minutes, and it may last for 6 hours. Salbutamol is the most commonly used selective β2 agonist. It is usually given through a nebuliser (10-20 mg in 4 ml of saline). An effect may be seen in 30 minutes, with maximum effect at 90-120 minutes. Salbutamol can be used alone or to augment the effect of insulin. Patients with acidosis may also be treated with intravenous sodium bicarbonate (500 ml of a 1.26% solution [37 mmol] over 60 minutes) although the benefit is uncertain and routine bicarbonate treatment for hyperkalaemia remains controversial.

*Management of severe hyperkalaemia should be undertaken in an inpatient setting with continuous cardiac monitoring

†Patients with moderate hyperkalaemia (serum potassium 6.0-6.5 mmol/l) should probably be admitted to hospital for supervised lowering of serum potassium

Fig 3 ECG changes in patients with hyperkalaemia

Fig 4 Algorithm for diagnosis of hyperkalaemia.
Thirdly, further interventions are undertaken to remove potassium from the body. Potent loop diuretics (for example, 40-80 mg of intravenous furosemide) enhance renal potassium excretion by increasing urine flow and sodium delivery to the distal nephron. However, diuretics only work if the patient has adequate renal function, and many patients with hyperkalaemia have acute or chronic renal failure. Cation exchange resins, which remove potassium from extracellular fluid via the gut in exchange for sodium, are also commonly used, although their effectiveness is debatable.34 They act more quickly when given as enemas (for example, calcium resonium 30 g) than when given orally (15 g four time a day); it may take 6 hours to achieve a full effect. Dialysis is the definitive treatment for patients with severe hyperkalaemia and advanced chronic kidney disease.

**Long term management of hyperkalaemia**

After acute treatment, measures should be established to prevent recurrence of hyperkalaemia. The first step is to carefully review the patient’s medication and to avoid or minimise drugs that increase potassium retention. Because ACE inhibitors and ARBs slow the progression of chronic renal disease, use of other measures to control the hyperkalaemia or dose reduction are preferable to discontinuing these drugs. Dietary advice to restrict potassium intake to 40-60 mmol a day is prudent. Diuretics may be effective in promoting renal potassium loss to prevent recurrence of hyperkalaemia. Thiazide diuretics may be used in patients with preserved renal function, but are usually ineffective when the glomerular filtration rate is less than 40 ml/min, when a loop diuretic such as furosemide is preferable. Fluudrocortisone may be used in patients with hyporeninaemic hypoaldosteronism. However, this drug can cause fluid retention and hypertension, and should be used with caution—particularly in patients with type 2 diabetes, who often have co-existing hypertension.

**QUESTIONS FOR ONGOING AND FUTURE RESEARCH**

- How important are the different risk factors for hyperkalaemia, and how does the clinician define them quantitatively in an individual?
- With increasing use of cardioprotective or renoprotective treatments that promote potassium retention, what is the best way to monitor potassium levels?
- Do patients with chronic hyperkalaemia actually achieve balance for potassium—if so, how is this balance achieved?
- Further understanding of the molecular pathways responsible for maintaining potassium concentration in extracellular fluid, to develop novel therapeutic strategies to treat life threatening hyperkalaemia.
Managing anaemia in critically ill adults

Timothy S Walsh, professor of critical care, Duncan LA Wynncoll, consultant in critical care, Simon J Stanworth, consultant haematologist

Anaemia (haemoglobin <120 g/l for women, and <130 g/l for men) is common in acutely unwell patients. Maintaining sufficient oxygen transport to the tissues is fundamental to survival and recovery from acute illness, and in the United Kingdom 8-10% of the blood supply is used to treat patients in intensive care. Red blood cells transport more than 97% of the oxygen content of blood—about 200 ml/l—and anaemia greatly reduces oxygen delivery, especially if patients also have cardiovascular and respiratory compromise.

Transfusion of donor (alloergic) red blood cells is the standard method for rapidly correcting anaemia in acutely unwell patients, but the risk-benefit balance of this intervention is the subject of continuing debate, controversy, and concern.

We highlight uncertainties in the management of anaemia in critically ill patients, especially in relation to the use of red cells, and summarise current evidence from observational studies and randomised trials. We focus on the management of anaemia in critically ill patients without active bleeding, such as those who are in adult medical and surgical intensive care units, high dependency units, and other acute units. We do not discuss the management of patients with major haemorrhage, for which recent evidence is available elsewhere.

How common is anaemia in patients with critical illness?

Observational studies have shown that anaemia affects 60-80% of patients cared for in intensive care units, and 50-70% develop moderate to severe anaemia (haemoglobin concentration <90 g/l) during their stay. Most patients have a normochromic, normocytic anaemia with high ferritin concentrations and low serum iron, transferrin, and transferrin saturation. Only 10-15% of patients have a history of chronic anaemia before admission to intensive care, which highlights the importance of acute factors in its development.

Why do critically ill patients become anaemic?

Unless modified by blood transfusions, haemoglobin values typically decrease by about 5 g/l/day during critical illness, and 20-50% of critically ill patients receive transfusions. Box 1 lists the factors that contribute to anaemia during critical illness. In individual patients several factors usually contribute in varying degrees. When intravenous fluids are given plasma volume expands and the haemoglobin concentration decreases without a major change in red cell mass. This is important to consider when resuscitating a patient (fig 1). Blood sampling typically results in the loss of 30-60 ml of blood each day, and loss from artificial circuits, such as haemofiltration circuits, or occult loss may increase daily losses. Several high quality observational studies have shown impaired erythropoiesis during critical illness. The healthy response to acute blood loss, the reticulocyte response, is usually absent, probably because of the failure of the kidneys to increase erythropoietin production and a hyporeactive bone marrow. These biochemical characteristics are almost identical to the anaemia of chronic disease, which suggests that they result from systemic inflammation. Absolute iron deficiency is rare, but many patients have a functional iron deficiency from redistribution of iron into macrophages and reticuloendothelial cells, which may limit availability of iron for red cell production. Infections and sepsis are major risks associated with blood transfusions.

Are there risks associated with blood transfusions?

Observational studies have found it difficult to measure clinical benefit from red cell transfusion in patients with acute severe illness and have often found higher complication rates in transfused patients than in otherwise similar patients who received fewer or no transfusions. These studies found associations between receiving red cells and a range of adverse outcomes including higher rates of hospital acquired infections, organ dysfunction, longer stays in the intensive care unit and hospital, and increased mortality. However, observational studies are open to confounding bias because patients who are more severely ill are more likely to die and also more likely to be transfused, so the association between transfusion and mortality may not be causal.

Several small randomised trials have explored the relation between red cell transfusion and complications, but most were inconclusive. The largest randomised trial to compare different haemoglobin transfusion “triggers” (the Transfusion Requirements In Critical Care, TRICC trial, described below) found that using red cells more restrictively was at least as effective as a more liberal approach. It found a trend towards lower mortality in patients treated with a restrictive approach, especially if they were younger or less severely unwell, and patients in the liberally transfused group had higher rates of organ dysfunction and cardiac complications.

venous catheter) are clinically useful triggers that signal the need to increase oxygen delivery. When faced with evidence of poor oxygenation, clinicians must decide whether to increase the cardiac output (with fluids or inotropic drugs, or both) or improve the oxygen carrying capacity of blood (with red cells). The lack of reliable clinical or laboratory tests to indicate when transfusion is needed means that clinicians rely heavily on the haemoglobin concentration as the primary trigger for transfusion. The problem is that the correct trigger haemoglobin is usually unknown for an individual patient and might vary depending on their clinical condition.

### Table 2 Useful clinical symptoms, signs, and tests when deciding if red cell transfusion is needed

What haemoglobin concentration should trigger blood transfusion in critically ill patients?

The best evidence on what haemoglobin concentration should trigger transfusions in critically ill patients comes from a well performed non-blinded multicentre Canadian trial published in 1999 (the TRICC trial; summarised in box 3), which is widely considered the most important trial in transfusion medicine. Patients with a haemoglobin 90 g/l or less were randomised to either a relatively high haemoglobin transfusion trigger of less than 100 g/l with a target of 100-120 g/l (the “liberal” group) or a lower haemoglobin transfusion trigger of less than 70 g/l with a target of 70-90 g/l (“restrictive” group). The findings strongly support using red cells only to maintain a haemoglobin concentration of 70-90 g/l, especially in younger or less severely ill patients. The generalisability of these findings is unclear, however, and this might explain why clinical practice still varies. This trial has never been replicated in adult critical care, and a recent Cochrane systematic review noted the need for further trials.21

We recommend using a haemoglobin transfusion trigger close to 70 g/l as the default position but to modify this using clinical judgment in individual patients. We consider a single unit transfusion followed by reassessment of the haemoglobin value before further transfusion to be best practice unless the patient is actively bleeding or has a haemoglobin concentration substantially lower than 70 g/l. Some evidence exists to support using a higher transfusion trigger than 70 g/l in the following clinical scenarios.

**Patients with chronic ischaemic heart disease**

Coronary blood flow occurs mainly during diastole. The heart muscle has a high metabolic rate and normally extracts 60-70% of available oxygen to meet its needs. If coronary stenoses limit blood flow it is logical to suppose that anaemia will increase the risk of myocardial ischaemia, especially if tachycardia and shock limit perfusion further. Several large cohort studies have found that in patients with chronic ischaemic heart disease haemoglobin concentrations less than 90 g/l were associated with higher mortality during surgery and critical illness.24 90-90 No high quality randomised trials have confirmed this association. A subgroup analysis of patients in the TRICC trial who had pre-existing ischaemic heart disease found a non-significant trend towards lower mortality for the liberally transfused group. However, in the entire study cohort the rates of new cardiac complications were lower in the restrictive group.21 A lack of high quality evidence means that clinicians have to make decisions on the basis of the severity of coronary artery disease in the individual patient, on whether electrocardiography shows evidence of ischaemia, and on whether coronary blood flow is likely to be adequate.

**Patients with acute coronary syndrome**

Several cohort studies have found associations between anaemia and higher mortality after acute coronary syndrome.22 14 15 but no evidence is available from randomised controlled trials to suggest what haemoglobin value should be targeted. The most recent highest quality cohort studies do not show benefit from transfusion when the haemoglobin concentration is more than 80 g/l, but the overall quality of evidence is low and controlled trials are needed, especially because bleeding and anaemia are both common in patients who are treated for acute coronary syndrome.24
We agree with current recommendations to keep the haemoglobin concentration no lower than 80-90 g/l in patients with an acute coronary syndrome, although the supporting evidence is weak and based largely on physiological reasoning.4 22

Patients with early sepsis

Patients with sepsis are at risk of inadequate oxygen delivery to the tissues, particularly during the first six to 12 hours after onset. After this time, abnormalities in the utilisation of cellular oxygen probably become more important than oxygen supply. One single centre, non-blinded, randomised controlled trial used oxygen saturation of less than 70% in central venous blood (measured via a central venous catheter) as a trigger for a resuscitation protocol that included giving red cells to keep the haemoglobin concentration more than 90-100 g/l.33 Fifty per cent more patients in the intervention group received blood during the first six hours of care compared with controls, but patients also received more fluids and inotropic drugs. The intervention improved hospital survival from 30.5% to 46.5%, but the relative importance of blood transfusion was uncertain. Until additional evidence emerges it is reasonable to consider transfusing patients with early sepsis to haemoglobin values of 90-100 g/l in addition to resuscitation with fluids and adrenergic drugs, but only if there is clear evidence that oxygen supply may be inadequate (oxygen saturation of <70% in central venous blood, or severe or worsening lactic acidosis). Once patients are haemodynamically stable, a haemoglobin of 70-90 g/l is probably adequate.

Acute neurological disease

The quality of evidence to guide transfusion in patients with intracerebral haemorrhage, thrombotic stroke, subarachnoid haemorrhage, and traumatic brain injury is low and no randomised trials exist.4 11. Anaemia and the need for blood transfusion are associated with greater disability and mortality in these patients, but clinicians must judge on a case by case basis whether blood transfusion is necessary. Using direct measures of brain oxygenation may help.4 24

Figure 2 presents an approach to making decisions about transfusion in critically ill adults.

What alternatives to blood transfusions are available to treat anaemia?

Several large well conducted randomised trials have evaluated the effect of using recombinant human erythropoietin, which is not currently licensed for use in this setting, to treat anaemia in people with critical illness.27 28 29 The dose and frequency of treatment, the use of supplemental iron, and the haemoglobin transfusion triggers used differed between trials. This treatment resulted only in a modest reduction in the use of red cells in early smaller trials, and in the largest most recent trial transfusion was not significantly reduced.21 Although thrombotic events increased, which is a concern, overall mortality decreased, especially in patients with trauma, so this treatment may have other beneficial effects.27

### ADDITIONAL EDUCATIONAL RESOURCES

**TIPS FOR NON-SPECIALISTS**

- Before giving a blood transfusion consider the potential risks and benefits for the individual patient
- Most critically ill patients can safely tolerate a haemoglobin concentration of 70-90 g/l
- If the patient is not bleeding a haemoglobin value of 70-80 g/l is a safe transfusion trigger, with a target value of 70-90 g/l
- In patients who are not bleeding transfuse a single unit of red cells and re-measure the haemoglobin concentration before considering more

**Resources for healthcare professionals**

- NHS Scotland ([www.learnbloodtransfusion.org.uk/](http://www.learnbloodtransfusion.org.uk/))—An interactive e-learning resource relating to safe transfusion practice, which is ideal for training of healthcare staff who prescribe or administer blood products
- **Resources for patients**

  - NHS Choices ([www.nhs.uk/Conditions/Blood-transfusion/Pages/Introduction.aspx](http://www.nhs.uk/Conditions/Blood-transfusion/Pages/Introduction.aspx))—UK based website providing information in lay terms on blood transfusions, when they are needed, and what questions to ask healthcare professionals when they recommend a blood transfusion

### BOX 3 SUMMARY OF KEY FINDINGS OF THE TRICC TRIAL

**PICO details**

**Population**

- Non-bleeding critically ill patients whose haemoglobin value was 90 g/l or less during the first three days in the intensive care unit

**Intervention and comparator**

- The trial compared a restrictive strategy (haemoglobin transfusion trigger 70 g/l; target value 70-90 g/l) with a liberal strategy (haemoglobin trigger 100 g/l; target value 100-120 g/l) for managing anaemia with blood transfusions during the intensive care unit stay

**Outcomes**

- The restrictive group received 54% fewer units of blood and 33% received no blood transfusions in the intensive care unit, whereas all of the liberal group were transfused
- The restrictive group showed a non-significant trend towards lower mortality (18.7% v 23.3%; P=0.11)
- The restrictive group had lower rates of cardiac complications (13.2% v 21.0%) and new organ failures (difference in multiple organ dysfunction score of 1 between the groups)
- The liberal group showed a trend towards higher rates of acute respiratory distress syndrome (11.4% v 7.7%)

**Predefined subgroup analyses**

- Younger patients (<55 years) and patients with lower illness severity during the first 24 hours in the intensive care unit (APACHE II score <20) had significantly better outcomes when they were in the restrictive group (these patients were more anaemic and received fewer blood transfusions)

**Subgroup analyses that were not predefined (post hoc analyses)**

- There was a trend for patients with known ischaemic heart disease to have better outcomes in the liberal group
- No differences in outcomes were seen in the subgroup of patients who were mechanically ventilated

**Uncertainties about the generalisability of the findings**

- The blood used was not leucodepleted. Transfused leucocytes may have adverse effects in critically ill patients and most countries now routinely leucodeplete blood before storage18
- The storage age of the blood was unknown. Longer storage times might affect patient outcomes, especially if the blood was not leucodepleted17
- The study could not prove that the restrictive approach was safe for all patient subgroups, especially those with heart disease and sicker older patients
- Improvements in critical care and blood processing over the past decade might mean the findings would be different if the trial were repeated now
A large multicentre trial in critically ill patients is comparing the effect of fresh red cells (stored for fewer than eight days) with red cells of standard age (typically 18-21 days’ storage) on mortality and other important outcomes (ABLE study; ISRCTN44287838).

A multicentre trial in patients who have undergone cardiac surgery is comparing the effect of transfusing red cells stored for up to 10 days with red cells stored for 21 days or more on mortality and other important clinical outcomes (RECESS study; NCT00991341).

A large multicentre trial in critically ill patients is comparing the effect of fresh red cells (stored for up to 10 days) with red cells stored for 21 days or more on mortality and other important clinical outcomes (RITRE2 trial; ISRCTN09239352), hip fracture surgery (FOCUS trial; NCT00707032), and intensive care (RELIEVE trial; NCT 0094112).

Several research trials and programmes are re-evaluating the effect of different transfusion triggers on patient outcomes—for example, in cardiac surgery (TiTRE2 trial; ISRCTN70923932), hip fracture surgery (FOCUS trial; NCT00707032), and intensive care (RELIEVE trial; NCT 0094112).

Laryngitis

John M Wood, ENT registrar¹, Theodore Athanasiadis, laryngologist², Jacqui Allen, laryngologist³

Laryngitis describes inflammation of the larynx, and a variety of causes result in the presentation of common symptoms. Laryngitis may be acute or chronic, infective or inflammatory, an isolated disorder, or part of systemic disease, and often includes symptoms such as hoarseness. Commonly, laryngitis is related to an upper respiratory tract infection and can have a major impact on physical health, quality of life, and even psychological wellbeing and occupation if symptoms persist. Overall, laryngitis incorporates a cluster of non-specific laryngeal signs and symptoms that can also be caused by other diseases. Consequently diagnosis can be difficult and requires correlation of history, examination, and, if necessary, specialised assessment, including visualisation of the larynx and stroboscopy. Acute laryngitis is typically diagnosed and managed at the primary care level. In at risk populations, or those with persisting symptoms, referral to a specialist otolaryngologist should be considered. The aim of this review is to assist non-specialists in assessing and managing people with laryngitis and to identify the cohort that requires specialist input.

What is laryngitis?
The larynx is a complex organ that is important for airway protection and maintaining safe swallowing and positive pressure in the pulmonary system. It is integral to cough, straining, and swallowing, and has immunological and even hormonal functions. Disease related changes in the larynx can impair some or all of these functions. The term laryngitis is descriptive and refers to inflammation of the larynx. It is typically used to describe acute infective laryngitis, one of the most common diseases of the larynx. However, a multitude of other causes of laryngeal inflammation present with similar signs and symptoms. Typically, laryngitis includes dysphonia, air wasting (excessive loss of air through the incompletely closed glottis resulting in a breathy voice), and pain or discomfort in the anterior neck, and it may include other symptoms such as cough, throat clearing, globus pharyngeus (feeling of a lump in the throat), fever, myalgia, and dysphagia.

How common is it?
The prevalence of laryngitis is difficult to estimate. A review conducted by the Royal College of General Practitioners in the United Kingdom in 2010 reported an average incidence of 6.6 cases of laryngitis and tracheitis per 100 000 patients (all ages) per week.¹

How is it assessed?
Laryngeal symptoms may have many causes. They are usually driven by four broad disease processes: inflammation, neoplastic and structural abnormalities, imbalance in muscle tension, and neuromuscular dysfunction.² Laryngeal symptoms arise from one or a combination of these processes. A careful history and examination is crucial in determining the primary factor and helping to identify other factors leading to persisting symptoms.

The first consideration in the initial assessment of patients with laryngeal symptoms should be airway patency. Patients with stridor or respiratory distress need urgent assessment in a setting where airway support can be provided quickly if needed. Having assessed the airway, the history should cover the nature and chronology of voice symptoms, any exacerbating and relieving factors, and the patient’s voice use and requirements. In addition to the description of vocal problems, it is important to ask about associated symptoms of dysphagia, odynophagia, otalgia, reflux, globus pharyngeus, weight loss, pulmonary health, and choking.

Box 1 outlines the red flag symptoms that should prompt an urgent referral to exclude malignancy. Contributing medical conditions or the effects of treatment should be considered, as should lifestyle factors, including smoking, diet, and hydration. The impact on quality of life and psychosocial wellbeing should also be addressed.

Investigations include a general head and neck examination covering the oral cavity, oropharynx, and neck, and an assessment of the patient’s voice. This can be done by way of a simple scale: grade 1 (subjectively normal voice), grade 2 (mild dysphonia), grade 3 (moderate dysphonia), grade 4 (severe dysphonia), and grade 5 (aphonic), with additional qualifiers used as necessary—for example, breathy, strained. Alternatively, a widely used grading system is the GRBAS (grade, roughness, breathiness, asthenia, strain) scale. It is a simple and reproducible method to assess voice change and quality. This tool grades hoarseness, roughness, breathiness, asthenia (weakness), and strain on a scale of 0-3, with 0 representing normal, 1 mild degree, 2 moderate degree, and 3 high degree. Either scale may be used by practitioners to track changes in voice over time and also allows other practitioners to understand the degree of voice dysfunction from notation.

What are the causes of acute laryngitis?
Acute laryngitis is commonly caused by infection (viral, bacterial, or fungal) or trauma.³ Inflammation and oedema of the larynx impairs vibration of the vocal folds, with
resulting symptoms. Inflammation may involve any area within the larynx, including the supraglottis (epiglottis, arytenoids, and false vocal folds), the glottis (true vocal folds), and subglottic regions. The larynx may be affected directly by inhaled material or by haematogenous spread, infective seclusions, or as a consequence of irritation from contact trauma—for example, coughing. Symptoms may persist but are usually self-limiting, with a duration of less than two weeks. In general practice, treatment is generally supportive, with voice rest, adequate hydration, and mucolytics.

Viral laryngitis
Viruses are the most common cause of acute laryngitis, most often rhinovirus, adenovirus, influenza, and parainfluenza. Other viruses should be considered, particularly in patients who are immunocompromised (for example, due to herpes species, human immunodeficiency virus, coxsackievirus). Rarely, severe infections such as herpes simplex can result in laryngeal erosion and necrosis.

Bacterial laryngitis
Bacteria are also an important cause of acute laryngitis, and distinction between viral and bacterial infections can be difficult. The two may coexist, with viral illness allowing opportunistic bacterial superinfection to occur. Commonly identified bacteria include Haemophilus influenzae B (HiB), Streptococcus pneumoniae, Staphylococcus aureus, β haemolytic streptococci, Moraxella catarrhalis, and Klebsiella pneumoniae. Production of pseudomembrane or serous casts, purulence, marked erythema, and co-involved distant sites (for example, lung, tonsils) are often suggestive of bacterial disease. Historically, diphtheria was associated with a pathognomonic grey membranous cast that could actually cause airway obstruction. With vaccination this is rarely seen nowadays. Viral illness may manifest blisters, particularly herpes zoster, and can be associated with nerve paresis involving the lower cranial nerves. Equally, erythema and pain disproportionate to the mucosal appearances can be representative of viral disease. Fever may be present in both, as can systemic symptoms. Reaction to antibiotics can indicate viral disease in retrospect—for example, production of rash when amoxicillin is given in the presence of Epstein Barr virus infection.

Unusual causes of bacterial laryngitis in developed nations include mycobacterial and syphilitic disease, although these are still seen in developing countries or areas with large immigrant populations. Diagnosis can be difficult, as lesions may appear ulcerative, mimic neoplasia or candidiasis, or have a non-specific inflammatory appearance. Ultimately tissue diagnosis is essential to assess for tumour, which is considerably common, or to identify acid-fast bacilli on microscopy. Suspicion should be high in patients from developing countries with high rates of tuberculosis and those who are immunocompromised.

Supraglottitis and epiglottitis—Owing to the rapid progression of airway compromise, especially in children, much of the literature on acute bacterial laryngitis concerns supraglottitis and epiglottitis, particularly in the context of H influenzae. Patients present with rapidly progressing odynophagia, dysphagia, hoarseness, drooling, and stridor. This constellation of symptoms indicates a high risk of impending airway compromise and requires emergency assessment and airway management. Treatment for less severe cases includes humidification through nebulised normal saline, or constant humidified oxygen, corticosteroids, intravenous antibiotics, and nebulised adrenaline. HiB vaccination has altered the epidemiology and incidence of supraglottitis and epiglottitis, most notably in the paediatric population, with a substantial decrease in presentations.

Fungal laryngitis
Laryngeal candidiasis is a common yet under-diagnosed disease, presenting in both immunocompromised and immunocompetent patients and accounting for up to 10% of presentations. Risk factors include recent use of antibiotics and use of inhaled corticosteroids. Laryngeal examination usually demonstrates whitish speckling of the supraglottis or glottis. At times, diffuse laryngeal erythema and oedema may be seen without these plaques. Candidiasis may mimic other disorders, particularly hyperkeratosis, leucoplaikia, and malignancy, and these must be ruled out by biopsy or imaging. Although such infections most often occur in immunocompromised patients, they can occur in patients with normal immunity when there are alterations to the mucosal barrier, such as after chemoradiotherapy, prolonged use of inhalers, or laryngopharyngeal reflux. Biopsy can be difficult to obtain and culture may take several weeks, although fungal elements may be detected more rapidly on Gram stains. Consequently some experts have recommended the diagnosis is implied from a combination of strong clinical suspicion with adequate treatment response to oral antifungal tablets and antifungal solution.

Phonotrauma
Laryngeal inflammation can arise from collision forces of the vocal folds. Such injury can occur with excessive voice use or misuse during phonation. Yelling, screaming, forceful singing, and strained voicing may result in diffuse inflammation and erythema within the larynx. Consequently those in professions with high vocal demands, such as professional singers, actors, and teachers are at much greater risk of developing voice disorders. Although injury is most often limited to the superficial layers of the vocal fold, and endoscopic findings may be minimal, wound healing after repeated episodes can lead to long term changes and persistent symptoms. The larynx may be traumatised in other ways, including blunt or penetrating trauma, chronic coughing, or habitual throat clearing. These may be acute or may persist, with development of chronic laryngitis.

How is acute laryngitis treated?
Management of laryngitis varies depending on the severity. Patients with acute airway compromise or presumed epiglottitis should be referred for urgent management. Most cases of acute laryngitis are self-limiting and typically resolve within two weeks. Management options include vocal hygiene and antibiotics. Vocal hygiene refers to measures such as voice rest, hydration, humidification, and limiting caffeine intake. These measures are invaluable in the symptomatic treatment of laryngeal inflammation. Care of the voice should be recommended to all presenting with vocal difficulties as this provides symptomatic relief and is good practice to carry forward, even as laryngitis resolves. Periods of voice rest may be as short as 48 hours or as long as a week, and a simple rule of thumb can be to recommend voice rest until patients find it comfortable to hum. Then modest speech can be resumed. Hydration is vital, particularly in those who snore or mouth-breathe at night. Hydration may be achieved just by chewing sugar-free gum, or increasing total fluid intake during waking hours (250 mL per waking hour). Caffeine is dehydrating and increases reflux and therefore exacerbates both snoring and pharyngolaryngeal irritation. Fewer than two standard expressos a day is recommended. Many sodas and “smart drinks” also contain high levels of caffeine.

Vocal difficulties can result from hyperfunctional vocal behaviours, which in professional voice users can limit or even end their career. High risk groups include singers, performers, and teachers. Holistic voice hygiene programmes encompass a multifactorial approach. Most programmes focus on four main tenets: dealing with the amount and type of voice use, reducing phonotraumatic behaviours, improving hydration, and enhancing lifestyle to improve vocal health, such as reducing caffeine and alcohol intake, smoking cessation, and managing medical conditions. The role of local lubrication, systemic hydration, control of laryngopharyngeal reflux, and allergies are often addressed. A study of teachers found such programmes demonstrated a reduction in vocal misuse and resulting voice symptoms. However, reviews conducted on the benefit of vocal hygiene found limited data for either therapeutic or preventive techniques.

Antibiotics
Treatment of acute laryngitis with antibiotics is widely debated, with frequent reports of inappropriate prescribing of antibiotics for upper respiratory tract infections. A Cochrane systematic review of two trials involving a total of 206 adults found no benefit in treating acute laryngitis with antibiotics, as measured by differences in objective voice scores at one and two weeks’ follow-up. The first included study compared a five day course of penicillin V with placebo and reported no difference in patient reported symptoms at 2-6 months’ follow-up. The second study compared erythromycin with placebo and found a subjective reduction in voice disturbance at one week and a reduction in cough at two weeks in the erythromycin group. Signs and symptoms such as persistent fever (>48 hours), purulent sputum, membrane formation, or associated distant disease should prompt consideration of antibiotic treatment.

When should people with laryngitis be referred?
Patients with acute airway compromise or suspected epiglottitis or supraglottitis should be assessed in hospital as an emergency. Acute laryngitis is often self limiting and typically resolves within two weeks. The persistence of laryngeal symptoms beyond three weeks is defined as chronic laryngitis. It can indicate additional laryngeal disease and warrants examination. Acute laryngitis may become chronic, with a shift in the underlying pathophysiology. It may be a direct consequence of the initial acute laryngitis episode or have a completely different or concomitant or superimposed cause. A recent retrospective study found that three quarters of patients referred to an otolaryngologist with an initial diagnosis of acute laryngitis had a different final laryngeal diagnosis. Importantly, nearly half the patients with laryngeal cancer had an initial diagnosis by their primary care doctor of either acute laryngitis or non-specific dysphonia. This highlights the need for adequate laryngeal examination by an otolaryngologist in all patients with persisting symptoms, or in those who generate a high degree of suspicion, such as heavy smokers.

There is debate as to how long dysphonia may be present before warranting laryngoscopy. Many otolaryngologists would recommend laryngoscopy if dysphonia is present for more than three weeks without an obvious cause, such as acute illness or intubation. Interestingly, guidelines from the American Academy currently state that direct laryngeal...
New diagnostic tools including the lateral flow pepsin assay or Peptest (RDBiomed, Hull, United Kingdom), and the Restech pharyngeal probe (Respiratory Technology Core, San Diego, CA) are currently in validation studies and may prove to be of clinical use in future. Several studies have identified pepsin as one of the injurious agents in laryngopharyngeal reflux, with injury compounded in the presence of an acidic environment. Pepsin can be endocytosed by hypopharyngeal cells and may be reactivated later. Furthermore, it is not inactivated until the pH is greater than 8 and retains around 20% activity at a pH of 6.8, the average pH of the laryngopharynx. Despite acknowledgment that reflux laryngitis is not merely an acid phenomenon, management still centres on high dose use of proton pump inhibitors (PPIs), both as a therapeutic and as a diagnostic technique. A significant percentage of patients with laryngopharyngeal symptoms fail to improve with use of PPIs and may require physical reflux barriers such as Gaviscon liquid (Reckitt Benckiser, Hull, United Kingdom). In addition, the duration of treatment with PPIs is uncertain. A recent systematic review, including eight randomised controlled trials, found only two studies where PPIs were significantly more effective than placebo. The studies concluded that the current body of literature is insufficient to make reliable conclusions about the benefits of PPIs in laryngopharyngeal reflux. Antisecretory drugs also present an important side effect profile, including bloating, epigastric discomfort, inhibition of calcium and magnesium absorption, atrophic gastritis, and drug induced acid hypersecretion. PPIs should only be prescribed for a defined period and then symptoms reviewed. Where symptoms remain, further investigation should be considered, including pH-metry, impedance, laryngoscopy, gastroscopy, manometry, and videofluoroscopic swallowing study, depending on the cluster of symptoms. Hyperacidity, association of symptoms with or after meals should prompt pH study with impedance. Where there is associated solid food dysphagia, gagging, or choking a videofluoroscopic assessment of swallowing is recommended. If symptoms are dyspeptic in nature (bloating, belching, food triggered) then gastroscopy may help.

Overall, the treatment of laryngopharyngeal reflux should include dietary and behaviour modification, with judicious use of antisecretory drugs. Liquid alginate preparations and H2 receptor antagonists have been used in combination with PPIs in recalcitrant cases. The role of laparoscopic fundoplication is well established in patients with GORD and typical symptoms. Some investigators recommend antireflux surgery for patients with laryngeal symptoms. However, a review of 893 consecutive patients who underwent a laparoscopic fundoplication identified 93 with throat symptoms. Those who experienced typical GORD symptoms in addition to “throat” symptoms improved similarly to those with only typical GORD symptoms of heartburn or regurgitation. Patients with objective evidence of GORD, dual channel pH monitoring and laryngeal examination suggesting laryngopharyngeal reflux, and only experiencing throat symptoms were less likely to benefit from surgery. Less than half in this group benefited from surgery, and patients should be counselled appropriately if this option is being considered. Failure to respond to optimal combined antireflux treatment should prompt consideration of alternative causes of laryngeal symptoms.

What are the causes of chronic laryngitis?

Chronic laryngitis is defined as laryngitis that persists beyond three weeks. It can be due to a range of different disease processes, ranging from inflammatory processes, such as allergic laryngitis and laryngopharyngeal reflux, to autoimmune disorders such as rheumatoid arthritis, and granulomatous disease such as sarcoidosis. Chronic laryngitis is less prevalent in primary practice but is the primary indication for referral. By definition, chronic laryngitis implies persistent laryngeal problems, and the glottis should be directly visualised in this situation. While a detailed description of each cause of chronic laryngitis is outside the scope of this review, box 2 summarises the features of the common causes of chronic laryngitis.

Laryngopharyngeal reflux/extraoesophageal reflux

Over the past 30 years it has been increasingly recognised that extraoesophageal manifestations of gastro-oesophageal reflux disease (GORD) may include laryngitis. Large population based studies have reported that patients with GORD are at increased risk for associated laryngeal or pulmonary complications. Symptoms of laryngopharyngeal reflux include non-specific laryngeal manifestations, such as hoarseness, dysphagia, odynophagia, globus pharyngeus, chronic cough, and throat clearing. Furthermore, laryngopharyngeal reflux has been associated with other conditions, such as vocal cord nodules, both premalignant and malignant changes in the larynx, and even sinusitis and otitis media. There is increasing evidence that the pathophysiology of laryngopharyngeal reflux differs from that of GORD, with patients affected by laryngopharyngeal reflux experiencing more daytime (upright) reflux without oesophagitis.

The prevalence of laryngopharyngeal reflux is difficult to determine, particularly as typical heartburn is absent in 57-94% of patients. However, it has been estimated to be present in 10% of patients presenting to an otolaryngologist and over half the patients referred with voice disorders. The diagnosis of laryngopharyngeal reflux is controversial as no ideal test is available. The pH of refluxate is not important. Recent studies have considered the utility of pH-metry with intraluminal impedance testing and symptom association probability scores. Impedance allows consideration of non-acid and mixed reflux episodes in relation to symptom generation. This improves temporal association of symptoms with reflux episodes of any pH, which may be relevant in atypical symptoms of reflux such as cough or globus pharyngeus. New diagnostic tools including the lateral flow pepsin...
Dysphonia associated with otalgia, stridor, neck mass, or dysphagia should be considered.

What role does neural dysfunction play in chronic laryngitis or dysphonia?

Dysphonia of duration more than three weeks requires direct laryngoscopy.

What is the role of targeted antireflux treatments such as pepsin inhibitors and the Linx system? (Linx is a circlet of magnets inserted at the lower oesophageal sphincter in a laparoscopic procedure designed to augment closing pressures).

Modulatory behaviour and modification or humidification are invaluable in symptomatic treatment of inflammatory laryngitis.

**QUESTION FOR FUTURE RESEARCH**

- What role does neural dysfunction play in chronic laryngitis or dysphonia?

**TIPS FOR NON-SPECIALISTS**

- Dysphonia of duration more than three weeks requires direct laryngoscopy.
- Dysphonia associated with otalgia, stridor, neck mass, or dysphagia should be considered related to malignancy until proved otherwise.
- Failure to respond to proton pump inhibitor treatment does not exclude a diagnosis of reflux laryngitis.

Viral meningitis
Sarah A E Logan, specialist registrar, Eithne MacMahon, consultant

Viral meningitis is common and often goes unreported. In the absence of a lumbar puncture, viral and bacterial meningitis cannot be differentiated with certainty, and all suspected cases should therefore be referred. Lumbar puncture and analysis of cerebrospinal fluid may be done primarily to exclude bacterial meningitis, but identification of the specific viral cause is itself beneficial. Viral diagnosis informs prognosis, enhances care of the patient, reduces the use of antibiotics, decreases length of stay in hospital, and can help to prevent further spread of infection. Over the past 20 years, vaccination policies, the HIV epidemic, altered sexual behaviour, and increasing travel have altered the spectrum of causative agents. In this review we outline the changing epidemiology, discuss key clinical topics, and illustrate how identification of the specific viral cause is beneficial. Neonatal meningitis may be a component of perinatal infection and is not covered here.

How common is viral meningitis?
Viral meningitis can occur at any age but is most common in young children. In the largest reported study, a 1966 birth cohort of 12000 children in Finland, the annual incidence of presumed viral meningitis was 219 per 100 000 in infants under 1 year and 27.8 per 100 000 overall in children under 14.4 In a smaller retrospective study, the incidence of aseptic meningitis in people aged 16 and over was lower at 7.6 per 100 000.5

Viral meningitis is a notifiable disease in England and Wales, but many cases undoubtedly go unreported.4 5 7 In 2005-6, 2898 people were admitted to hospital with a diagnosis of viral meningitis, 10 times the number of cases available to differentiate between acute viral meningitis and bacterial meningitis, so all suspected cases should be referred to hospital.

What causes it?
As a consequence of mumps, measles, and rubella vaccination, enteroviruses have supplanted mumps as the most common cause of viral meningitis in children (box 1).4 6 Enteroviruses are said to account for 80% of cases in adults, but a wider range of causes is increasingly implicated.8 9 Often no cause is identified; among 144 consecutive adults with aseptic meningitis, only 72 had a confirmed diagnosis. Enteroviruses were most common, accounting for 46%, followed by herpes simplex virus type 2 (31%), varicella zoster virus (11%), and herpes simplex virus type 1 (4%).5

What is the initial approach to the patient?
Viral meningitis and bacterial meningitis are both characterised by acute onset of fever, headache, photophobia, and neck stiffness, often accompanied by nausea and vomiting.1 9 Untreated patients with bacterial meningitis show progressive deterioration in mental status, whereas spontaneous recovery is usual in viral cases. At initial presentation, no reliable clinical indicators are available to differentiate between acute viral meningitis and bacterial meningitis, so all suspected cases should be referred to hospital.

Particular caution is warranted with young children, in whom meningitis is manifest as fever and irritability, without, as a rule, evidence of meningeal irritation.9 Neck stiffness and photophobia may also be absent in adults.10 Assessment should include evaluation for possible encephalitis, suggested by seizures, reduced Glasgow coma score, or focal neurological signs. Suspected encephalitis warrants empirical antiviral treatment with intravenous aciclovir. History and examination can yield clues as to viral causes (box 2).

How is it diagnosed?
Analysis of cerebrospinal fluid is needed, and lumbar puncture should be done unless it is contraindicated. Whether prior computed tomography imaging is needed is controversial, and guidance is now available (see box 2).11 12 Viral meningitis in itself is not associated with abnormalities on imaging. C reactive protein concentration and peripheral blood white cell count can be helpful but
do not reliably differentiate between possible causes. A blood glucose concentration is essential and should be collected immediately before lumbar puncture.° Cerebrospinal fluid needs to be processed promptly to avoid depletion of cell counts during transport or storage. Although characteristically associated with a mononuclear pleocytosis, neutrophils may predominate initially in viral meningitis (table 1). In 138 children with aseptic meningitis, 57% had a polymorphonuclear predominance that persisted beyond 24 hours.°° The usual initial approach to viral diagnosis (table 2) is to test the cerebrospinal fluid for enteroviruses, herpes simplex virus, and varicella zoster virus by using polymerase chain reaction technology, estimated to be threefold to 1000-fold more sensitive than routine viral culture.° Identification of a viral cause has been shown to be beneficial, facilitating reduced administration of antibiotics and decreased length of stay in hospital.°° Enteroviruses Enteroviruses are by far the most common cause of viral meningitis; they account for most cases, at all ages, in which the cause is identified.°° 3 The term enteroviruses refers to the mode of transmission rather than the symptoms of infection. Indeed, infections with these ubiquitous viruses are mostly asymptomatic. They can cause systemic infections, however, and have a proclivity to be neuroinvasive. The enteroviruses encompass Coxsackie A and B viruses, echoviruses, polioviruses, and the more recently identified viruses designated by number, such as enterovirus 71.°°° Almost any of the enterovirus types can give rise to neurological manifestations ranging from aseptic meningitis to meningoencephalitis and paralytic poliomyelitis. Coxsackie B viruses and echoviruses account for most cases of enterovirus meningitis. Enteroviral typing is essential to identify and monitor outbreaks.°°° Who gets it? Infants and young children with no immunity are most susceptible to enteroviruses, and the incidence decreases with age. Infection is seasonal in temperate climates—highest in summer and autumn—but high all year round in tropical and subtropical climates.°°° Clinical features and management Meningitis may be accompanied by mucocutaneous manifestations of enterovirus infection, including localised vesicles such as in hand, foot, and mouth disease; herpangina; and generalised maculopapular rash. Most cases that present clinically with meningitis are self limiting and carry a good prognosis. Nevertheless, enteroviral meningitis causes considerable morbidity, with moderate or high fever despite antipyretics and several days of severe headache warranting opiate analgesia.°°° Abrupt deterioration in mental status or seizures may be caused by progression from meningitis to meningoencephalitis.°°°

BOX 1 VIRAL MENINGITIS: CAUSES TO CONSIDER 1 3

- All patients
  - Enteroviruses
  - Herpes simplex viruses (HSV-2 and HSV-1)
  - Varicella zoster virus (VZV)
  - Human immunodeficiency virus (HIV)
  - Epstein-Barr virus (EBV)

- Unvaccinated/incomplete vaccination course
  - Mumps virus

- Immunocompromised host
  - Cytomegalovirus (CMV)

- Travel history
  - West Nile virus (Americas, Africa, West Asia, Australia, mainland Europe)
  - Saint Louis encephalitis virus (United States)
  - Tick-borne encephalitis viruses (mainland Europe and Asia)

- Contact with rodent droppings or urine
  - Lymphocytic choriomeningitis virus (LCMV)

BOX 2 APPROACH TO THE PATIENT

- History
  - Classic symptoms—fever, headache, photophobia, neck stiffness
  - Associated symptoms—rash, sore throat, swollen glands, vomiting, genitourinary symptoms
  - Illness in contacts
  - Sexual history
  - Travel abroad
  - Risk factors for HIV
  - Mumps immunisation status
  - Compromised immunity
  - Exposure to rodents/ticks

- Examination
  - Classic signs:
    - Fever, nuchal rigidity
    - Absence of focal neurological signs; mental status intact
  - Rash
  - Lymphadenopathy
  - Pharyngitis
  - Parotid swelling
  - Genital herpes

- Imaging before lumbar puncture?
  - Recommended if any of the following are present:
    - Immunocompromised host:
    - Immunosuppressive treatment
    - Immunodeficiency (for example, HIV)
    - History of central nervous system disease—mass lesion, stroke, focal infection
    - New onset of seizure(s)—within one week of presentation
    - Focal neurological deficit
    - Abnormal level of consciousness manifest by:
      - Glasgow coma score (GCS) ≤12 or
      - Fluctuating conscious level (drop in GCS ≥2)
    - Papilloedema

Fig 1 Notifications of viral meningitis for England and Wales compared with hospital episodes in England
No specific antiviral treatment is available, and management is conservative. Immunoglobulin replacement has a role in patients with hypogammaglobulinaemia, who are prone to severe and chronic enteroviral disease.

**Herpes simplex viruses (HSV-2, HSV-1)**

Confusion sometimes arises when herpes simplex virus is detected in the cerebrospinal fluid of a patient with clinical meningitis. Recognising that herpes simplex virus meningitis and encephalitis are discrete entities in the immunocompetent host, rather than part of a continuous spectrum, is essential. Whereas herpes simplex virus encephalitis is a life threatening medical emergency warranting empiric antiviral treatment, herpes simplex virus meningitis is a self limiting condition in patients with normal immunity.

**Who gets it?**

Herpes simplex virus now ranks second among the causes of viral meningitis in adolescents and adults in developed countries. Primary herpes simplex virus meningitis is a complication of primary genital herpes, especially with HSV-2. By definition, primary herpes simplex virus infection is the first infection with either virus type in the absence of pre-existing antibodies to HSV-1 or HSV-2. In the most comprehensive study, 36% of 126 women and 13% of 63 men with primary genital HSV-2 infection had meningeal symptoms.

Non-primary infection includes first episodes in the presence of pre-existing antibodies to HSV-1 or HSV-2 and recurrences. Unlike primary infection, non-primary genital infection with herpes simplex virus is rarely accompanied by aseptic meningitis. HSV-2 meningitis may also occur in the absence of clinical genital herpes. Of 69 patients with meningeval symptoms and HSV-2 detected in the cerebrospinal fluid, 82% had neither a history of genital herpes nor active genital lesions.

As a consequence of the increasing incidence of genital herpes, clinical cases of herpes simplex virus meningitis in the United Kingdom are set to increase. The rate of childhood infection with HSV-1 is declining; a documented drop in seropositivity rates among 10-14 year olds from 34% (1986-7) to 24% (1994-5) has occurred. Thus, in the absence of previous oral herpes simplex virus infection, an increasing proportion of young people are likely to have symptomatic primary genital herpes simplex virus infections and hence meningitis.

*First line tests.
Clinical features and management
In addition to fever and symptoms of meningitis, constitutional symptoms of primary herpes infection may occur, with malaise and clinical features of genital herpes simplex virus infection. Whereas autonomic dysfunction occurs in 2% of cases of primary genital herpes, sacral radiculomyelitis (manifest as urinary retention, constipation, occurs in 2% of cases of primary genital herpes, sacral occur, with malaise and clinical features of genital herpes constitutional symptoms of primary herpes infection may

### CASE STUDIES

**Patient 1**
A 37 year old woman presented with headache, neck stiffness, photophobia, and vomiting. She had been increasingly unwell over the preceding 10 days and had sought medical advice for severe dysuria on more than one occasion; she was receiving treatment for a presumptive urinary tract infection. On examination, she was febrile with signs of meningism. Vulvular inspection showed no evidence of vesicles. Analysis of cerebrospinal fluid showed white cells 62×10^3/l (90% lymphocytes), protein 1.6 g/l, and glucose 2.8 mmol/l; no concomitant serum sample was available. Polymerase chain reaction detected HSV-2 DNA in the cerebrospinal fluid, consistent with the diagnosis of herpes simplex virus meningitis. She was treated with intravenous aciclovir 10 mg/kg eight hourly for six days, followed by oralvalaciclovir 1 g eight hourly for two weeks. Her symptoms resolved gradually, and she was discharged after six days.

At the genitourinary clinic two months later, acute and convalescent type specific serology confirmed recent primary HSV-2 (HSV-2 lgG positive; HSV-1 lgG negative; anti-HSV lgM positive) infection in association with meningitis and presumed urethritis. Her husband also attended; although asymptomatic, he had serological evidence of previous HSV-2 infection. One year later she has had recurrent genital herpes but not meningitis.

**Patient 2**
A 32 year old woman presented with a three day history of headache, fever, and photophobia. She had perianal tenderness, and her boyfriend had noticed a rash. On examination, she was febrile with signs of meningism. Viral culture of cerebrospinal fluid showed no evidence of viruses. Analysis of cerebrospinal fluid showed white cells 67×10^3/l (99% lymphocytes), protein 1.2 g/l, and glucose 2.8 mmol/l. No concomitant serum sample was available. Polymerase chain reaction detected HSV-2 DNA in the cerebrospinal fluid. She received oral valaciclovir 1 g eight hourly for seven days and opiates for severe headache. Her symptoms gradually resolved over three weeks.

- US Centers for Disease Control, Viral “aseptic” meningitis (www.cdc.gov/nCIDod/dvdv/rev/viral meningitis.htm)—Explains enteroviral meningitis well
- Meningitis Research Foundation (www.meningitis.org.uk)—Information mainly about bacterial meningitis

HSV-2 meningitis can recur, especially in women with primary genital infection. Clinical recurrences have been described in 20-50% of cases, both with and without genital symptoms. Indeed HSV-2 has been implicated in recurrent benign lymphocytic meningitis (including Mollaret’s meningitis), a syndrome characterised by spontaneous recovery after each of at least three episodes of aseptic meningitis. HSV-2 (and occasionally HSV-1) DNA and herpes simplex virus type specific antibodies have been detected in the cerebrospinal fluid of up to 85% of patients. Although antiviral treatment with aciclovir, valaciclovir, or foscarnet is indicated for the treatment of first episode genital herpes, therapeutic trials have yet to be done in herpes simplex virus meningitis. Evidence is lacking, but early treatment might decrease the viral burden, speed resolution of symptoms, and reduce the risk of recurrence.

Patients with herpes simplex virus meningitis should be referred to a sexual health clinic after recovery. However, the diagnosis of herpes simplex virus meningitis and possible associations with genital herpes may come as a shock to the patient, and this needs to be discussed sensitively at the earliest appropriate opportunity. Many people harbour genital herpes simplex virus infection and intermittently shed virus without ever having symptoms. Infection can thus be spread unknowingly to sexual contacts. The timing of transmission is unpredictable; it may occur only after several years within a monogamous sexual relationship.

**Varicella zoster virus**
Aseptic meningitis is a recognised but rare complication of primary infection with varicella zoster virus (varicella). It is more commonly seen in association with reactivation of varicella zoster virus (zoster) and can also occur in the absence of cutaneous lesions. Among 21 patients with varicella zoster virus meningitis, more than 50% had no skin manifestations.

No specific recommendations for varicella zoster virus meningitis exist beyond the usual treatment for zoster.

**Human immunodeficiency virus**
Primary HIV infection is an important cause of aseptic meningitis. Symptoms occur in up to 17% of cases of HIV seroconversion and may be associated with faster disease progression. Other features of primary HIV infection—lymphadenopathy, rash, dermatitis, gastrointestinal disturbances, oral candidiasis, and pharyngitis—should be sought. Atypical lymphocytes may be seen in the blood film in both primary HIV and Epstein-Barr virus infections (both are causes of viral meningitis). The neurological symptoms generally resolve over several weeks. Early diagnosis may benefit intimate contacts, as the risk of transmission of HIV is greater in the early stages of infection.

**Mumps**
Meningitis is by far the most common neurological manifestation of mumps virus infection. Before widespread immunisation, mumps was a common cause of meningitis, which occurred in 15% of patients with mumps. Mumps meningitis can precede or follow the parotid swelling, and 50% of cases occur in the absence of parotitis. Meningitis is more common in male than female patients. The recent epidemic among young adults was associated with more than 100 cases of mumps meningitis in England in 2004–6.

Spontaneous intracerebral haemorrhage

Rustam Al-Shahi Salman, MRC clinician scientist and honorary consultant neurologist,1 Daniel L Labovitz, assistant professor2, Christian Stapf, assistant professor of neurology3

Spontaneous (non-traumatic) intracerebral haemorrhage accounts for at least 10% of all strokes in the United Kingdom, but the incidence is higher in some ethnic groups. Intracerebral haemorrhage may present with a sudden focal neurological deficit or a reduced level of consciousness, after which it kills about half of those affected within one month and leaves most survivors disabled.

Although early case fatality after spontaneous intracerebral haemorrhage has not changed over the past two decades, brain imaging has illuminated the pathophysiology of intracerebral haemorrhage and its various causes, such that the term primary intracerebral haemorrhage now seems antiquated. Improving prevention of intracerebral haemorrhage in primary care and its outcome in secondary care is especially important in view of trends towards a rising incidence of intracerebral haemorrhage in an ageing population.

How should intracerebral haemorrhage be distinguished from other causes of stroke?

No clinical scoring system has been shown to reliably differentiate intracerebral haemorrhage from ischaemic stroke. Timely brain imaging is the key to recognising intracerebral haemorrhage. Computed tomography detects symptomatic intracerebral haemorrhage within minutes of symptom onset and up to one week thereafter; magnetic resonance imaging with gradient-recalled echo sequences reliably differentiates infarction from haemorrhage more than one week after onset of stroke.

Diagnostic imaging distinguishes intracerebral haemorrhage from other types of intracranial haemorrhage (fig 1), although intracerebral haemorrhage may extend into other intracranial compartments. This distinction is important, because the causes, prognosis, and treatment vary according to the location of intracranial haemorrhage.

What are the detectable causes of intracerebral haemorrhage?

The major risk factors for spontaneous intracerebral haemorrhage are systemic arterial hypertension, excess alcohol consumption, male sex, increasing age, and smoking. These risk factors may lead to secondary vascular changes, such as small vessel disease and arterial aneurysms, which may eventually cause intracerebral haemorrhage. Pioneer postmortem studies from the era when non-invasive brain imaging was not widely available suggested that many intracerebral haemorrhages, especially those in deep brain locations, were caused by deep perforating artery lipohyalinosis attributable to chronic hypertension. However, a systematic review found a much weaker association between hypertension before a stroke and deep intracerebral haemorrhage.

Systematic investigation of selected patients with intracerebral haemorrhage identifies an underlying arteriovenous malformation in about 20% and an aneurysm in about 15%, so the focus should be on identifying these potentially treatable causes of recurrent intracerebral haemorrhage (table 1).

As a result of the rising use of thrombolytic, antiplatelet, and anticoagulant drugs their association with intracerebral haemorrhage is also increasing, such that many patients have several concurrent causes, none of which is either necessary or sufficient to have caused the intracerebral haemorrhage.

How should we investigate intracerebral haemorrhage?

After a radiological diagnosis of intracerebral haemorrhage, some routine investigations are essential (box 1), but international guidelines reflect the lack of consensus on which patients to image further, and how and when to do so. Doctors are most likely to further investigate younger patients with intracerebral haemorrhage. But patient age, comorbidities, and location of intracerebral haemorrhage are unreliable means of predicting cause with certainty, so we recommend further imaging in all patients who can tolerate it and whose prognosis is not bleak (box 1).

Early computed tomography angiography is a quick and widely available first line investigation for an underlying aneurysm or arteriovenous malformation or fistula when these diagnoses are suspected (table 1), but only a few small studies have investigated its sensitivity (88-100%) and specificity (95-100%) compared with catheter angiography. Arteriovenous malformations are likely to be under-ascertained in clinical practice because catheter angiography is not used systematically and needs to be repeated to show some arteriovenous malformations.

Magnetic resonance imaging is useful for detecting venous thrombosis acutely and for detecting underlying tumours and cavernous malformations at least two months after the intracerebral haemorrhage. Magnetic resonance imaging may also detect some foci of haemosiderin, known as microbleeds, but the diagnostic importance of their detection and distribution is still under investigation.

What is the outcome after intracerebral haemorrhage?

The main predictors of death within one month are older age, low score on the Glasgow coma scale on admission, increasing volume of intracerebral haemorrhage, and deep intracerebral haemorrhage.
infratentorial intracerebral haemorrhage location, and intraventricular extension. These five prognostic factors may help to assess the risk of death within one month for individual patients using the total intracerebral haemorrhage score (table 2), which has been externally validated although it may not be as accurate as other scales. Intracerebral haemorrhage volume can be estimated easily using the “ABC/2” method. This method entails identifying the axial computed tomography slice with the largest area of intracerebral haemorrhage, and halving the product of its maximum width (A in figure 2), the width perpendicular to A (B in figure 2), and the depth (C, which is determined by multiplying the number of slices on which intracerebral haemorrhage was visible by the slice thickness of the relevant part(s) of the brain computed tomogram).

Intracerebral haemorrhage volume can be estimated easily using the “ABC/2” method. This method entails identifying the axial computed tomography slice with the largest area of intracerebral haemorrhage, and halving the product of its maximum width (A in figure 2), the width perpendicular to A (B in figure 2), and the depth (C, which is determined by multiplying the number of slices on which intracerebral haemorrhage was visible by the slice thickness of the relevant part(s) of the brain computed tomogram).

Early neurological deterioration is explained by various mechanisms, including perihaematomal oedema and haematoma expansion, which affects about a third of patients within the first 24 hours of onset (figure 2, C and D). However, withdrawal of care and “do not resuscitate” orders may have an equally powerful influence.

The location and underlying cause of an intracerebral haemorrhage partly determine the long term risk of recurrent haemorrhage, dependence in daily activities, and death. The annual risk of recurrent intracerebral haemorrhage is about 2% for deep intracerebral haemorrhage without an identified cause and about 10% for lobar intracerebral haemorrhage. However, the annual risk of recurrent intracerebral

**Box 1: Tests to investigate intracerebral haemorrhage**

**Essential**
- Full blood count
- Coagulation screen: prothrombin time, activated partial thromboplastin time, d-dimers
- Electrolytes, urea, creatinine, liver function tests
- Glucose
- Inflammatory markers (C reactive protein, erythrocyte sedimentation rate)
- Toxicology screen
- Electrocardiography
- Chest radiography
- Pregnancy test

**Dependent on patient characteristics, prognosis, and characteristics of intracerebral haemorrhage**
- Computed tomography angiography or venography
- Magnetic resonance imaging
- Catheter angiography

*Adapted from the American Heart Association’s guidelines*
haemorrhage from a ruptured arteriovenous malformation varies from about 4% to about 34% according to its vascular anatomy, which is another reason for angiographic investigation of intracerebral haemorrhage. 15 People with intracerebral haemorrhage are also at risk of subsequent ischaemic stroke, at a rate of about 1% a year.16

How should we treat intracerebral haemorrhage?

General management of stroke
Guidelines and systematic reviews recommend that patients with spontaneous intracerebral haemorrhage should be managed either in a stroke unit, or in an intensive care unit if they need ventilation or intracranial pressure monitoring.9 10 16 17 International guidelines are available for the management of hydration, nutrition, hyperglycaemia, and hyperthermia, prevention of complications, and early rehabilitation.9 10 Although the risk of epileptic seizure(s) is higher within the first week of lobar than deep intracerebral haemorrhage (about 14% vs about 4%),18 no evidence exists to support the use of prophylactic antiepileptic drugs after intracerebral haemorrhage.9 10

Because of the shortage of high quality evidence on how blood pressure should be managed after acute intracerebral haemorrhage, clinical guidelines recommend various blood pressure reduction regimens.9 10 A recent, randomised pilot trial of adults who had a systolic blood pressure 150-220 mm Hg within six hours of onset of intracerebral haemorrhage found intensive blood pressure reduction to be feasible, well tolerated, and associated with a reduction in haematoma growth,19 although clinical benefit remains to be established in ongoing clinical trials (see web extra table on bmj.com). For now, the use of antihypertensive agents seems necessary if there is end organ damage (though the desirable parameters are uncertain),20 but randomisation in relevant clinical trials is recommended if there is uncertainty.

Small randomised controlled trials have not found significant beneficial or harmful effects from the acute administration of corticosteroids,21 mannitol,22 glycerol,23 or a free radical-trapping neuroprotectant.24

Haemostatic drugs
Because volume of intracerebral haemorrhage influences outcome and about a third of acute intracerebral haemorrhages enlarge within 24 hours of onset,25 early treatment with a haemostatic drug might improve outcome by limiting expansion of the haematoma. Phase II trials of intravenous recombinant activated factor VII were initially promising (fig 3), although their sample sizes were small and the outcomes for the placebo group were surprisingly poor. Recombinant activated factor VII did not improve clinical outcome in a larger phase III trial; the broader inclusion criteria, problems with randomisation, and preponderance of arterial thromboembolism after recombinant activated factor VII could all explain why this treatment shows no overall clinical benefit in a meta-analysis (risk ratio 0.91, 95% confidence interval 0.72 to 1.15; fig 3).17

Neurosurgical haematoma evacuation
Evacuation of the haematoma may show the underlying cause in the cavity or lead to the identification of amyloid angiopathy if cortical biopsy is performed, but the dilemma is whether surgery improves outcome.
**Infratentorial intracerebral haemorrhage**

Guidelines recommend that neurosurgical intervention should be considered immediately for people with a cerebellar haemorrhage if it is causing deterioration in consciousness, brainstem compression, or hydrocephalus as a result of obstruction of the drainage pathways for cerebrospinal fluid (fig 4). Ventricular drainage may be sufficient to alleviate hydrocephalus, but further neurological deterioration requires evacuation of the haematoma. These recommendations are based on case series, in which outcome has been so good that randomised trials are unlikely to be undertaken.

*30 day case fatality as percentages (95% CI) as indicated by scores:
Score 1: 13 (5 to 28)
Score 2: 26 (13 to 45)
Score 3: 72 (55 to 84)
Score 4: 97 (83 to 99)
Score 5: 100 (61 to 100)

There were no patients with a score of 6.

**Supratentorial intracerebral haemorrhage**

One systematic review found that evacuation of spontaneous supratentorial intracerebral haemorrhage improves outcome (odds ratio 0.71, 95% confidence interval 0.58 to 0.88; fig 5), although another did not. However, about 14% of patients with supratentorial intracerebral haemorrhage would need to have neurosurgical evacuation for one to avoid death or dependence, and these estimates are not robust because of the modest quality of most of the trials, methodological differences between them, and losses to follow up in the largest trial. A subgroup of patients with superficial lobar intracerebral haemorrhage within 1 cm of the cortical surface seemed to benefit in the STICH trial and is being studied further in the STICH 2 trial. Thrombolytic treatment of intraventricular extension from a spontaneous intracerebral haemorrhage is also the subject of ongoing randomised trials (see web extra table on bmj.com).

Treatments for specific causes

Some causes of intracerebral haemorrhage should not be missed because their treatment may improve outcome.

**Aneurysms and arteriovenous malformations**

One small randomised trial supports immediate evacuation of some intracerebral haematomas caused by aneurysm rupture, with concomitant clipping of the aneurysm. A large randomised controlled trial of coiling versus clipping for ruptured arterial aneurysms that could be occluded by either of these treatments has shown that coiling is less likely to result in death at five years despite a higher risk of rebleeding after coiling. Although a primary prevention trial for unruptured arteriovenous malformations is under way (www.arubastudy.org), there are no randomised trials of intervention for ruptured arteriovenous malformations or cavernous malformations.

**Fig 3 Forest plot of the effect of recombinant activated factor VII on death or dependence at 90 days after acute spontaneous infratentorial haemorrhage (dependence defined as score 4-5 on modified Rankin scale). Adapted with permission from a Cochrane review.**
Intracranial venous thrombosis

Data from two randomised controlled trials show a reduction in the risk of death or severe disability after anticoagulation for cortical vein or venous sinus thrombosis.\(^{41}\) Although the benefit of anticoagulation was based on relatively small trials, expert opinions favour immediate anticoagulation,\(^{39}\) which does not seem to precipitate or worsen clinically important intracerebral haemorrhage.

Haemorrhage associated with antithrombotic drugs

Guidelines state that when intracerebral haemorrhage occurs in patients taking oral anticoagulants, these drugs should be stopped and their effects urgently reversed, although surprisingly little evidence exists about the best method of doing so.\(^{3}\) \(^{30}\) Although intravenous vitamin K is given in most circumstances, it is slow to act, so either prothrombin complex concentrate or fresh frozen plasma are given to immediately replenish vitamin K dependent coagulation factors.\(^{39}\) The benefits of antiplatelet or even anticoagulant drugs may outweigh their risks after intracerebral haemorrhage for patients at very high risk of myocardial infarction or ischaemic stroke,\(^{39}\)\(^{35}\) but for now, whether to restart these drugs at 7–10 days after an intracerebral haemorrhage should be decided on a patient by patient basis.

Infective endocarditis

Septic emboli may cause cerebral mycotic aneurysms, which may in turn lead to intracerebral haemorrhage if left untreated.

Other medical treatments

The enthusiasm for medical treatment of acute intracerebral haemorrhage has resulted in several ongoing trials to reduce haematoma expansion (blood pressure lowering, recombinant activated factor VII in subgroups, and platelet infusions for antiplatelet associated intracerebral haemorrhage) or to reduce adverse consequences of intracerebral haemorrhage (thrombolysis for intraventricular extension of intracerebral haemorrhage, anti-inflammatory drugs, statins, free radical scavengers, and iron chelators).

What about secondary prevention?

Guidelines recommend that survivors of intracerebral haemorrhage should stop smoking and limit their alcohol consumption.\(^{9}\) \(^{30}\) A large randomised controlled trial found that after the acute phase of intracerebral haemorrhage a reduction in blood pressure (with an angiotension converting enzyme and a diuretic, if tolerated) was beneficial in preventing future vascular events.\(^{41}\) For an average systolic blood pressure reduction of 12 mm Hg, the risk of recurrent intracerebral haemorrhage may fall by up to 76%.\(^{45}\)

Conclusion

Randomised trials, systematic reviews, and international guidelines find that stroke units and secondary prevention with blood pressure reduction benefit people with intracerebral haemorrhage. Unfortunately, randomised trials of acute medical and surgical interventions do not conclusively support their routine use in clinical practice. Because the outcome after intracerebral haemorrhage is still extremely poor, ongoing trials are reason for optimism (see web extra table on bmj.com), and should be advocated in clinical practice.\(^{44}\)\(^{45}\)

Cauda equina syndrome

Chris Lavy, honorary professor and consultant orthopaedic surgeon, Andrew James, specialist registrar, James Wilson-MacDonald, consultant spine surgeon, Jeremy Fairbank, professor of spine surgery

An understanding of cauda equina syndrome is important not only to orthopaedic surgeons and neurosurgeons but also to general practitioners, emergency department staff, and other specialists to whom these patients present. Recognition of the syndrome by all groups of clinicians is often delayed as it presents with bladder, bowel, and sexual problems, which are common complaints and have a variety of causes. Patients may not mention such symptoms because of embarrassment or because the onset is slow and insidious.

Cauda equina syndrome is a clinical area that attracts a high risk of litigation. Although symptoms have poor predictive value on their own for the syndrome, it is important to document the nature and timing of bladder, bowel, and sexual symptoms (along with any associated clinical findings), particularly if they are new, especially in those with a history of back pain and associated leg pain, and to make a timely referral for appropriate investigation and expert treatment.

This review aims to highlight cauda equina syndrome as a possible clinical diagnosis, review the evidence for an emergency surgical approach, and maintain an awareness of the medicolegal issues that surround the condition.

What is cauda equina syndrome and how common is it?

Cauda equina syndrome results from the dysfunction of multiple sacral and lumbar nerve roots in the lumbar vertebral canal. Such root dysfunction can cause a combination of clinical features, but the term cauda equina syndrome is used only when these include impairment of bladder, bowel, or sexual function, and perianal or “saddle” numbness. 

A retrospective review in Slovenia found an annual incidence of cauda equina syndrome resulting from intervertebral disc herniation of 1.8 per million population. Using US data on annual incidence of symptomatic disc herniation (1500 per million population), the author estimates that each year 0.12% of herniated discs are likely to cause cauda equina syndrome. We suspect this is an underestimate and are conducting our own review in the United Kingdom, but if these figures are even approximately correct then most UK general practitioners are unlikely to see even one true case caused by intervertebral disc herniation in their career.

How does cauda equina syndrome present and what symptoms suggest it?

A history of perianal sensory loss and sphincter disturbance, with or without urinary retention, suggests the presence of cauda equina syndrome (figure 1 illustrates the anatomy of the lower lumbar and sacral spine showing the cauda equina). Three classic patterns of presentation have been described.

It can present acutely as the first symptom of lumbar disc herniation (type 1); as the endpoint of a long history of chronic back pain with or without sciatica (type 2); or insidiously in a more chronic way with slow progression to numbness and urinary symptoms (type 3). Most clinicians now divide cauda equina syndrome into two clinical categories: cauda equina syndrome with retention, in which there is established urinary retention; and incomplete cauda equina syndrome, in which there is reduced urinary sensation, loss of desire to void, or a poor stream, but no established retention or overflow. The slower the presentation, the better tolerated the symptoms are and the less likely the patient is to be alarmed. Patients with pre-existing bladder and incontinence problems resulting from other disease may also present late.

What causes cauda equina syndrome?

The commonest cause of cauda equina syndrome in our practice and the focal causative condition in the literature is compression arising from large central lumbar disc herniation at the L4/5 and L5/S1 level. Parke and colleagues suggest that there is an area of relative hypovascularity at the proximal portion of the cauda equina. Blood supply alterations resulting from nerve root pressure may therefore be of greater importance in this region of the cauda equina than elsewhere, with rapid changes allowing less adaptation than those of a slower onset.

Patients may be predisposed to cauda equina syndrome if they have a congenitally narrow spinal canal or have acquired spinal stenosis arising from a combination of degenerative changes of the disc and the segmental posterior joints with consequent thickening of the ligamentum flavum and narrowing of the available canal cross section. Numerous other less common causes of cauda equina syndrome have been reported—for example, spinal injury with fractures or subluxation. Spinal neoplasms of metastatic or primary origin can cause compression, usually accompanied by

**SUMMARY POINTS**

- Cauda equina syndrome is rare, but devastating if symptoms persist
- Clinical diagnosis is not easy and even in experienced hands is associated with a 43% false positive rate
- The investigation of choice is magnetic resonance imaging
- Once urinary retention has occurred the prognosis is worse
- Good retrospective evidence supports urgent surgery especially in early cases
- Litigation is common when the patient has residual symptoms

**CLINICAL DIAGNOSIS OF CAUDA EQUINA SYNDROME**

- Dysfunction of bladder, bowel, or sexual function
- Sensory changes in saddle or perianal area

**Other possible symptoms**

- Back pain (with or without sciatic-type pains)
- Sensory changes or numbness in the lower limbs
- Lower limb weakness
- Reduction or loss of reflexes in the lower limbs
- Unilateral or bilateral symptoms

**SOURCES AND SELECTION CRITERIA**

We searched Medline using the search term “cauda equina syndrome”. In addition, we used our personal reference archives and consulted other experts.
marked pain and often as part of a chronic condition. Infective causes with abscess formation or bony involvement, either within the spinal canal or impinging on it, may also cause cauda equina syndrome. The spine is the most commonly affected skeletal site for tuberculosis, and Pott’s paralysis is well documented. A wide range of iatrogenic causes are reported, including manipulation, spinal anaesthesia, postoperative complications such as haematoma or gelfoam implanted to protect the dura. Other space-occupying lesions, such as nerve derived tumours, schwannomas, ependymomas, facet joint cysts, perineural Tarlov cysts, haemangiomas, vena varix, and hydatid cysts are also recognised.

What features on examination suggest cauda equina syndrome?
When cauda equina syndrome is suspected a neurological examination of the legs should be performed, including perianal sensation and an assessment of anal tone (table). This is easily done in the lateral position: perianal sensation can be tested from the outside in towards the sphincter using a gentle gloved finger stroke and, if there is any uncertainty, a folded tissue and an unfolded paper clip. After this, a rectal examination can be performed. Loss or diminution of the bulbocavernous reflex (whereby stimulation of the glans, penis, or clitoris causes reflex contraction of the anal sphincter) is suggestive of cauda equina syndrome as the reflex is mediated through the sacral roots.

How should suspected cauda equina syndrome be investigated?
Recently published guidelines for the management of patients with back pain and neurological signs recommend urgent surgical referral for suspected cauda equina syndrome. Clinical diagnosis of cauda equina syndrome even by resident neurosurgeons has a 45% false positive rate, so accurate confirmatory imaging is important. In the United Kingdom magnetic resonance imaging (MRI) is the imaging modality of choice. It does not define bone as clearly as computed tomography (CT) but is better at showing soft tissues such as intervertebral disc, ligamentum flavum, dural sac, and nerve roots. In resource poor settings where neither MRI nor CT is available myelography can be useful in showing the presence and site of compression of the cauda equina. Figures 2 and 3 show examples of cauda equina on MRI scans.

Fig 1 Anatomy of the lower lumbar and sacral spine showing the cauda equina

How is cauda equina syndrome treated?
When a patient has clinical features of cauda equina syndrome and an MRI scan shows a potentially reversible cause of pressure on the cauda equina then current consensus recommends surgical decompression. This article will not review management of all the conditions leading to cauda equina syndrome, and some causes such as tumour clearly require detailed assessment of the nature and extent of the pathology. However, most cases of cauda equina syndrome are caused by herniation of the lumbar disc, for which the surgery indicated is decompression at the level of the herniation, usually involving discectomy. The operation can be very demanding technically, and great care is needed to avoid causing further damage to nerve roots or tearing tightly compressed dura.

Is surgery for cauda equina syndrome urgent?
The urgency of surgery remains controversial. When there is pressure on the cauda equina causing loss of sphincter control it would be understandable to think that the ideal treatment would be to remove the pressure as soon as possible with surgery. Ethical considerations will not allow this hypothesis to be tested by a randomised study, and it is very difficult to prove by literature review of retrospective and cohort studies (level 3 evidence) for two reasons. Firstly, the time of onset of symptoms is difficult to specify. Thus it is difficult to define the delay between symptoms and surgery. Secondly, any discussion is muddied by many published (mainly retrospective) series containing a mix of patients with both incomplete cauda equina syndrome and cauda equina syndrome with retention. The authors of two recent reviews argue that only incomplete cauda equina syndrome requires emergency surgery to try to stem the deterioration in bladder function. They conclude that in patients with cauda equina syndrome with retention the clinical outcome is poor anyway and bears no relation to timing of surgery. Thus these patients can wait until an elective surgical list the next morning rather than having a potentially difficult operation in the middle of the night, when circumstances are less than optimal.

Two other recently published UK series have found that outcome is independent of the timing of surgery. Incontinence at presentation is a poor prognostic feature in the largest prospective series.

A review that is widely quoted suggests that intervention less than 48 hours after the onset of symptoms will produce a better outcome than intervention delayed for longer than this. These data have been selectively reanalysed and suggest that the outcome for both types of cauda equina syndrome (with retention, or incomplete) is better with

Fig 2 Left: MRI scan showing compression of the cauda equina (arrow) due to a large posterior disc herniation at L4/5. Right: MRI scan showing a large disc herniation at L5/S1 (arrow) bulging posteriorly and compressing the cauda equina syndrome.
interventions within rather than after 24 hours. In a further analysis of the selected retrospective series, the authors noted that of 47 patients having surgery within 24 hours, 41 (87%) recovered normal bladder function, whereas of 46 patients having surgery later than 24 hours, only 20 (43%) recovered normal bladder function.75

A recent meta-analysis supports the view that early surgery is related to better results with incomplete cauda equina syndrome, but the case for cauda equina syndrome with retention is less certain.6 We urge the establishment of a multicentre outcome study with clear clinical entry points and clear separation of incomplete cases and those with retention.

QUESTIONS FOR FUTURE RESEARCH
- Multicentre outcome studies are needed to define which subgroups of cauda equina syndrome may benefit from emergency surgery and which do not need such urgent treatment
- Such studies may also develop prognostic indicators such as the length and degree of compression of the cauda equina
- Qualitative research is needed to determine appropriate questions and appropriate language to inquire about sensation in intimate areas

TIPS FOR NON-SPECIALISTS
- Be alert to the development of new symptoms of perianal sensory change or bladder symptoms in patients with an increase in back pain or sciatica
- Be aware that cauda equina syndrome can arise insidiously when patients who have had back and leg pain for a long time develop bladder symptoms gradually
- Establish the most appropriate channel for referral or further investigation in suspected cases in your specialty
- Make sure that clinical documentation is clear and well recorded

A PATIENT’S PERSPECTIVE
I wasn’t that concerned at first. I had just sneezed. I hadn’t even lifted anything heavy. The sudden, searing lower back pain was unpleasantly familiar to me and it usually got better by itself. I didn’t notice anything unusual until I started to get pins and needles in both my feet.

And then, after painfully struggling to the toilet, I remember wiping myself with the toilet paper and it feeling decidedly odd—not completely numb but distant. It was my refusal to admit to numbness that fooled my general practitioner. He asked if I could feel him touching me, not noticing anything unusual until I started to get pins and needles in both my feet.

What are the medicolegal implications of cauda equina syndrome?
Persisting cauda equina syndrome has a devastating effect on personal and social life, and its mismanagement is one of the commonest causes for litigation in spinal surgery. Most patients are young to middle aged and in work before they develop cauda equina syndrome, so the size of claims is large. The presence of residual symptoms means that many of these patients are unable to work and have genitourinary and bowel symptoms. From 1997 to 2006 the NHS Litigation Authority dealt with 107 cases in England in which care in hospital had been compromised (NHS Litigation Authority, personal communication, 2008). Extrapolating from previous data, we would expect about 100 new cases of cauda equina syndrome annually in England, suggesting that at least 10% of cases involve litigation. The NHS Litigation Authority reported that between 1997 and 2006 in 35% of litigation cases the primary complaint was against the emergency department and in 52% it was against the inpatient management team (personal communication as above). In the remaining cases the primary complaints were against other clinical areas, such as outpatients.

The responsible clinician in the litigation cases was in orthopaedics in 52% of cases, the emergency department in 27%, and neurosurgery in 8%; in the remaining cases the responsible clinician varied across various specialties.

JF and JW-MacD have prepared 22 medical negligence reports in cases of cauda equina syndrome over the past five years. The average delay to diagnosis was 67 hours and to treatment 6.14 days. These delays were attributed to orthopaedic surgeons in 32% of cases, general practitioners in 18%, and others in 14%, but in 34% of cases there was no clear case to answer. Fourteen per cent of patients had received their treatment within 24 hours and 32% within 48 hours. All patients had moderate or severe bowel and genitourinary symptoms. Most also had persisting back pain that would probably have occurred whatever the timing of surgery. Doctors who manage patients with spinal disorders need to be aware of cauda equina syndrome and its possible complications.

Ventilator associated pneumonia

John D Hunter, consultant in anaesthetics and intensive care

Ventilator associated pneumonia is the most common nosocomial infection in patients receiving mechanical ventilation, and it accounts for about half of all antibiotics given in the intensive care unit (ICU).1 Its reported incidence depends on case mix, duration of mechanical ventilation, and the diagnostic criteria used. It occurs in 9–27% of mechanically ventilated patients, with about five cases per 1000 ventilator days.2 The condition is associated with increased ICU and hospital stay and has an estimated attributable mortality of 9%.3

A number of evidence based strategies have been described for the prevention of ventilator associated pneumonia, and its incidence can be reduced by combining several in a care bundle.4

The purpose of this review is to update readers on the diagnosis, management, and prevention of this serious infection.

Ventilator associated pneumonia is a hospital acquired pneumonia that occurs 48 hours or more after tracheal intubation.5 It can usefully be classified as early onset or late onset pneumonia. Early onset pneumonia occurs within four days of intubation and mechanical ventilation, and it is generally caused by antibiotic sensitive bacteria. Late onset pneumonia develops after four days and is commonly caused by multidrug resistant pathogens. However, patients who have been in hospital for two or more days before intubation will probably harbour organisms more commonly associated with late onset pneumonia, regardless of the duration of ventilation.

What causes ventilator associated pneumonia

The principal risk factor for the development of ventilator associated pneumonia is the presence of an endotracheal tube.6 These tubes interfere with the normal protective upper airway reflexes, prevent effective coughing, and encourage microaspiration of contaminated pharyngeal contents. The importance of the endotracheal tube is emphasised by the incidence of pneumonia being significantly lower for non-invasive ventilation via a tight fitting facemask.7 Reintubation after unsuccessful extubation also increases the risk of pneumonia.8

Most cases are caused by microaspiration of contaminated oropharyngeal secretions.9 The oropharynx becomes rapidly colonised with aerobic Gram negative bacteria after illness, antibiotic treatment, or hospital admission as a result of alterations in host defences and subsequent changes in bacterial adherence to mucosal surfaces. These contaminated secretions pool above the cuff of the trachea or tracheostomy tube and slowly gain access to the airway via folds in the wall of the cuff.10 A bacterial biofilm, which is impervious to systemic antibiotics, gradually forms on the inner surface of the endotracheal tube and serves as a nidus for infection.11 Ventilator cycling propels pathogen rich biofilm and secretions to the distal airways. The size of the biofilm and the virulence of the bacteria within it contribute to the risk of infection, but it is the host’s immune response that determines whether parenchymal infection and ventilator associated pneumonia will develop.

Critical illness is associated with immunosuppression, and this increases susceptibility to nosocomial infection.12 Neutrophils are central to the body’s response to most bacterial infections, and mechanically ventilated patients have neutrophil dysfunction and impaired phagocytosis. Recent work by Morris and colleagues examined neutrophil function in patients with a high clinical suspicion of ventilator associated pneumonia. They found that patients who had significantly reduced phagocytic activity secondary to the overexpression of the inflammatory anaphylotoxin C5a, excess levels of which cause neutrophil dysfunction.13 Further work by the same group suggests that this C5a driven immunosuppression precedes the acquisition of nosocomial infection and is not merely a coincidental finding.14

What are the risk factors for developing ventilator associated pneumonia?

Patients who are nursed in the supine position have an increased risk of pneumonia, presumably because of the increased likelihood of gastric aspiration.15 Enteral feeding via a nasogastric tube may cause reflux of gastric contents and increase the risk of aspiration, but most intensive care physicians would agree that the benefits of providing adequate nutrition outweigh the increased risk of pneumonia.

Because the risk of developing pneumonia increases with duration of mechanical ventilation, modifiable factors associated with prolonged intubation such as oversedation or lack of protocol driven weaning increase the likelihood of pneumonia.16

How is ventilator associated pneumonia diagnosed?

Accurate diagnosis remains a challenge, with no consensus on a reference “gold standard” definition. Clinical diagnosis lacks sensitivity and specificity, leading to both overdiagnosis and underdiagnosis of the condition.17

Sources and selection criteria

I searched various sources to identify relevant evidence on the definition, epidemiology, and management of patients with ventilator associated pneumonia. These included PubMed, the Cochrane Library, and conference proceedings. I searched www.clinicaltrials.gov for current research.
the difficulties of establishing an accurate diagnosis, a high clinical suspicion of pneumonia should lead to the immediate administration of appropriate antibiotics. Delays in antimicrobial treatment increase mortality.6 7

Despite the lack of a universally agreed definition, ICU physicians generally agree that pneumonia should be suspected when there are new or persistent infiltrates on chest radiography plus two or more of the following:6:

- Purulent tracheal secretions
- Blood leucocytosis ($>12 \times 10^9$ white blood cells/L) or leucopenia ($<4 \times 10^9$ white blood cells/L)
- Temperature greater than 38.3°C.

The Hospitals in Europe Link for Infection Control through Surveillance (HELICS) criteria are widely used for surveillance of ventilator associated pneumonia rates in Europe (fig 1). Ventilator associated pneumonia is categorised as pneumonia (PN) 1-5 depending on the microbiological method used to make the diagnosis.

Making the diagnosis can be a challenge because many conditions commonly encountered in critically ill patients—such as pulmonary oedema, pulmonary haemorrhage, and acute respiratory distress syndrome—can mimic the signs and symptoms of pneumonia. Many ventilated patients have infiltrates on chest radiography that are not attributable to infectious pathology (fig 2), and the presence of a new infiltrate only marginally increases the likelihood of ventilator associated pneumonia (summary likelihood ratio 1.7; 95% confidence interval 1.1 to 2.5).1 Purulent tracheal secretions are often secondary to tracheobronchitis rather than parenchymal infection, and alterations in white cell count and fever symptoms can be caused by sepsis outside of the respiratory system.

Postmortem studies of patients suspected of having ventilator associated pneumonia suggest that using clinical criteria alone for diagnosis produces 30-35% false negative results and 20-25% false positive results.8 Because of this lack of sensitivity and specificity, it is good practice to obtain microbiological samples of lower respiratory tract secretions before antibiotics are started. Samples can be obtained invasively or non-invasively. Invasive sampling methods include bronchoalveolar lavage (BAL), protected specimen brushing, and increasingly blind “mini-BAL.” Mini-BAL, which is also referred to as non-bronchoscopic BAL or blind BAL, is performed using specially designed catheters that allow sampling of the distal airways via the tracheal tube. Because a bronchoscope is not needed it is quick and technically simple, with culture results that are comparable to other lavage methods.9 Invasively obtained samples are analysed quantitatively to differentiate oropharyngeal contaminants (which are present at low concentrations) from higher concentrations of infecting organisms. The diagnostic threshold is $10^4$ colony forming units/mL for protected specimen brushing and $10^5$ colony forming units/mL for BAL. However, bronchoscopically directed sampling may miss the portion of lung worst affected by disease, so its sensitivity and specificity vary greatly (11-77% and 42-94%).10 11 Sampling can also be performed non-invasively, and the tracheal aspirates analysed quantitatively or qualitatively. This technique also misses many cases of pneumonia, with a reported sensitivity of 56-69% and a specificity of 75-95%.12

The relative benefits of non-invasive and invasive techniques for obtaining samples and differentiating between airway colonisation and true infection are still unclear. Although one French randomised uncontrolled study showed a reduction in mortality when an invasive diagnostic strategy was used;13 five other trials found no differences in hospital mortality, length of stay, or duration of mechanical ventilation when compared with non-quantitative culture of endotracheal aspirates.14 A randomised trial by the Canadian Critical Care Trials Group randomised 740 patients with suspected ventilator associated pneumonia to undergo either BAL and quantitative culture or tracheal aspiration with non-quantitative culture of the specimens. No significant difference was seen between groups in the primary outcome (28 day mortality; 18.9% and 18.4%; P=0.94), days alive without antibiotics, or length of stay.15 A recent systematic review of qualitative versus quantitative analysis concluded that quantitative analysis was not associated with reduced mortality, reduced length of stay in intensive care, or higher rates of antibiotic change.16

Several biomarkers have been investigated for diagnosing ventilator associated pneumonia, including procalcitonin, C reactive protein, and a glycoprotein known as soluble triggering receptor expressed on myeloid cells type 1 (sTREM-1).26 The expression of sTREM-1 on phagocytes is strongly upregulated by exposure to bacteria. Although sTREM-1 concentrations are raised in BAL fluid from patients with ventilator associated pneumonia, the discriminatory value of this test is poor.27 Procalcitonin, a calcitonin precursor hormone, is secreted in response to bacterial infection. Although it lacks sensitivity and specificity for the accurate diagnosis of pneumonia, its serial measurement may help reduce antibiotic exposure.28 C reactive protein also lacks sufficient sensitivity and specificity for the diagnosis of pneumonia, but it can be useful for assessing the appropriateness of antibiotic treatment.29

**Which organisms are associated with ventilator associated pneumonia?**

To select the optimal antibiotic treatment it is essential to be aware of the organisms commonly associated with ventilator associated pneumonia. Most cases are bacterial in origin (table) and several organisms are often involved.30 The clinical relevance of fungal and viral pneumonia is still poorly understood.

The duration of mechanical ventilation before the onset of pneumonia is an important determinant of the likely pathogen. Pneumonia that occurs within four days of intubation is typically caused by antibiotic sensitive community bacteria such as *Haemophilus* spp, streptococci including *Streptococcus pneumoniae*, and meticillin sensitive *Staphylococcus aureus*. Later infection is more commonly caused by multidrug resistant pathogens, including *Pseudomonas aeruginosa*, *Acinetobacter* spp, and meticillin resistant *S aureus*. However, it is increasingly recognised that patients who have been in recent close contact with the healthcare system are more likely to develop infection with multidrug resistant organisms. Hospital admission for two or more days during the 90 days before the development of ventilator associated pneumonia, chronic haemodialysis, residence in a nursing home, and intravenous antibiotics or chemotherapy within the past 30 days all increase the likelihood of extremely drug resistant bacterial infection.31

The pathogens associated with ventilator associated pneumonia also depend on case mix, underlying comorbidity, hospital, and type of ICU.32 Each individual unit must collect continuous microbiological surveillance data to ensure optimal empirical antibiotic treatment of suspected pneumonia.
Which antibiotics are used to treat ventilator associated pneumonia?

A high clinical suspicion of pneumonia should lead to the immediate administration of appropriate empirical antibiotics. Ideally, airway samples for microbiological analysis should be taken before administration of antibiotics as long as this does not seriously delay treatment because delayed or inappropriate initial antimicrobial treatment is associated with excess mortality.16 35

Choose initial antibiotics on the basis of the results of local surveillance data and patient specific factors such as severity of illness, duration of hospital stay, and previous antibiotic exposure. Involvement of the local microbiologist is mandatory.

Although no optimal regimen has been identified, the chosen drug(s) should have a high degree of activity against aerobic Gram negative bacilli. Guidelines issues by the British Society for Antimicrobial Chemotherapy recommend co-amoxiclav or cefuroxime for patients with early onset infections who have not previously received antibiotics and have no other risk factors for multidrug resistant pathogens.14 In those who have previously received antibiotics or who have other risk factors, a third generation cephalosporin (cefotaxime or ceftriaxone), a fluoroquinolone, or piperacillin-tazobactam would be appropriate. Late onset pneumonia is more commonly associated with drug resistant bacteria, particularly P aeruginosa. To date, no specific antibiotic or regimen has been proved to be superior in the management of patients with ventilator associated pneumonia secondary to P aeruginosa, and acceptable treatment options include ceftazidime, ciprofloxacin, meropenem, and piperacillin-tazobactam. When meticillin resistant S aureus is a possibility, vancomycin or linezolid should be included in the antibiotic regimen. Although linezolid penetrates lung tissue better than vancomycin, a recent meta-analysis of randomised controlled trials suggest that it is no better than vancomycin.17

Combination antibiotic treatment does not seem to be better than empirical broad spectrum monotherapy, which is cheaper and exposes patients to fewer antibiotics.14 A de-escalation strategy should be used once the results of antimicrobial susceptibility tests are available. Antibiotics can be safely discontinued after eight days if an adequate clinical response is suggested by a resolution in the signs and symptoms of active infection (such as a reduction in C reactive protein, white cell count, and temperature, plus an improvement in oxygenation).18

Can ventilator associated pneumonia be prevented?

Although prevention of pneumonia is a vital part of the management of patients undergoing invasive mechanical ventilation, many studies of strategies and interventions that significantly reduce ventilator associated pneumonia rates fail to show a significant benefit in clinical outcomes, such as length of stay, duration of mechanical ventilation, or mortality.17 This is probably because it is difficult to accurately diagnose ventilator associated pneumonia and many preventive measures simply reduce airway colonisation and not invasive infection.

The three main ways of preventing pneumonia are to reduce colonisation of the aerodigestive tract with pathogenic bacteria, prevent aspiration, and limit the duration of mechanical ventilation. Best results are seen by using various combinations (bundles) of interventions in all mechanically ventilated patients.4 Recent guidance from the National Institute for Health and Clinical Excellence recommends that all bundles include oral antisepsis and nursing in the semirecumbent position.18

Reducing airway colonisation

Selective decontamination of the digestive tract and oral decontamination both aim to decrease the bacterial load of the digestive tract. Oral decontamination using antiseptics such as chlorhexidine seems to lower the risk of ventilator associated pneumonia (relative risk 0.61, 0.45 to 0.82),19 especially when combined with thorough mechanical cleaning of the oral cavity. Selective decontamination involves the oral and gastric administration of non-absorbable oral antibiotics (usually polymyxin, tobramycin, and amphotericin B) plus the intravenous administration of a broad spectrum antibiotic. Despite large meta-analyses showing a reduction in the incidence of pneumonia,40 selective decontamination is not widely used in the United Kingdom because of worries about the emergence of antibiotic resistance and increased incidence of Clostridium difficile infection. However, there is no evidence to support these concerns.

Microbial biofilms rapidly form on the luminal surface of endotracheal tubes and act as a reservoir for infection. Because silver has broad spectrum antimicrobial activity, coating the endotracheal tube with silver reduces bacterial colonisation and biofilm formation. A recent prospective randomised controlled study comparing traditional endotracheal tubes with silver coated ones showed a significant relative risk reduction of 35.9% (3.6% to 69%) in the occurrence of ventilator associated pneumonia with silver tubes.41 However, no benefit was seen on the duration of intubation, duration of stay in intensive care, or mortality.

Preventing aspiration

All patients without specific contraindications should be nursed in the semirecumbent position, with the head raised at 45°.42

Secretions that have pooled above the cuff of the tracheal tube can be removed by subglottic secretion drainage using specially designed tubes with a separate dorsal lumen that opens directly above the cuff. A meta-analysis of five prospective studies found this technique to be effective in preventing ventilator associated pneumonia (relative risk 0.51, 0.37 to 0.71) in patients expected to need more than 72 hours of mechanical ventilation.44 Recently introduced endotracheal tubes feature an ultrathin polyurethane cuff membrane that has narrower longitudinal folds when inflated, which limits microaspiration.45 A retrospective study reported a reduction in ventilator associated pneumonia rates from 5.3 per 1000 ventilator days to 2.8 per 1000 ventilator days after introduction of these tubes (P=0.0138),46 although more robust studies are lacking.

Limiting duration of mechanical ventilation

The duration of mechanical ventilation is strongly associated with the development of pneumonia. Therefore, strategies aimed at reducing the duration of tracheal intubation may reduce the incidence of pneumonia. Oversedation prolongs mechanical ventilation and should be avoided by careful assessment of sedation status and daily interruption of sedation if appropriate.11 Weaning protocols have also been shown to hasten discontinuation of mechanical ventilation.48 Although tracheotomy is often advocated to aid earlier weaning from respiratory support, little evidence exists to suggest that early tracheotomy reduces the incidence of pneumonia.49
Two or more serial chest radiographs or computed tomograms suggestive of pneumonia for patients with underlying cardiac or pulmonary disease. In patients without underlying cardiac or pulmonary disease one definitive chest radiograph or computed tomogram is sufficient.

And at least one of the following:
- Fever >38˚C with no other cause
- Leucopenia (4x10^9 white blood cells/L) or leucocytosis (12x10^9 white blood cells/L)

And at least one of the following (or at least two if clinical pneumonia only = PN4 and PN5):
- New onset of purulent sputum or change in character of sputum (colour, odour, quantity, consistency)
- Cough, dyspnoea, or tachypnoea
- Suggestive auscultation (rales or bronchial breath sounds), rhonchi, wheezing
- Worsening gas exchange (for example, oxygen desaturation, increased oxygen requirements, or increased ventilation demand)

And according to the used diagnostic method:
- PN1: Positive quantitative culture from minimally contaminated lower respiratory tract specimen – bronchoalveolar lavage specimen ≥10^4 colony forming units/mL
- PN2: Positive quantitative culture of lower respiratory tract (tracheal aspirate) with a threshold of 10^5 colony forming units/mL
- PN3: Positive culture related to no other source of infection – positive pleural fluid culture, pulmonary abscess with positive needle aspiration, positive histology, or positive exams for pneumonia with virus or particular organism (such as Aspergillus)
- PN4: Positive sputum culture or non-quantitative lower respiratory tract culture
- PN5: No positive microbiology

ADDITIONAL EDUCATIONAL RESOURCES FOR HEALTHCARE PROFESSIONALS

UNANSWERED QUESTIONS AND ONGOING RESEARCH
- Is the incidence of ventilator associated pneumonia a useful quality indicator in intensive care? There is an increasing demand to use this parameter as such, but the lack of a gold standard definition and the paucity of studies showing a clinically meaningful improvement with apparent reduction in pneumonia suggest that this should be resisted
- Do aerosolised antibiotics have a role in the management of patients with ventilator associated pneumonia?
- Do probiotics prevent ventilator associated pneumonia?
- Do immunomodulatory agents have a role in the management of patients with ventilator associated pneumonia?
### Distribution of organisms isolated from cases of ventilator-associated pneumonia by bronchoscopic techniques in 24 studies (1989-2000) including 1689 episodes and 240 pathogens*

Pneumothorax describes the presence of gas within the pleural space, between the lung and the chest wall. It remains a globally important health problem, with considerable associated morbidity and healthcare costs. Without prompt management pneumothorax can, occasionally, be fatal. Current research may in the future lead to more patients receiving ambulatory outpatient management. This review explores the epidemiology and causes of pneumothorax and discusses diagnosis, evidence based management strategies, and possible future developments.

How common is pneumothorax?
Between 1991 and 1995 annual consultation rates for pneumothorax in England were reported as 24/100 000 for men and 9.8/100 000 for women, and admission rates were 16.7/100 000 and 5.8/100 000, respectively, in a study analysing three national databases. The overall incidence represents a rate of one pneumothorax a year in an average sized general practice population. Across the United Kingdom this equates to around 8000 admissions for pneumothorax each year, accounting for 50 000 bed days given an average length of stay of just under one week. These admissions alone have estimated costs of £13.65m for the National Health Service. Annual costs in the United States have been estimated at $130m.

What are the types of pneumothorax?
Pneumothorax is categorised as primary spontaneous, secondary spontaneous, or traumatic (iatrogenic or otherwise). Traumatic pneumothorax is out of the remit of this review and will not be discussed.

The distinction between primary and secondary pneumothorax is based on the absence or presence of clinically apparent lung disease. Primary and secondary pneumothorax are distinct groups regarding morbidity and mortality, rates of hypoxia at presentation, and recommended management. Although primary pneumothorax is not associated with known lung disease, most affected patients have unrecognised lung abnormalities that may predispose to pneumothorax. A small case-control study found that emphysema-like changes were identified on computed tomography in 81% of 27 non-smokers with primary pneumothorax compared with 0% in the control group of 10 healthy volunteers who did not smoke. Secondary pneumothorax is associated with considerably more morbidity and mortality than primary pneumothorax, in part resulting from the reduction in cardiopulmonary reserve in patients with pre-existing lung disease.

Tension pneumothorax is a life threatening complication that requires immediate recognition and urgent treatment. Tension pneumothorax is caused by the development of a valve-like leak in the visceral pleura, such that air escapes from the lung during inspiration but cannot re-enter the lung during expiration. This process leads to an increasing pressure of air within the pleural cavity and haemodynamic compromise because of impaired venous return and decreased cardiac output. Treatment is with high flow oxygen and emergency needle decompression with a cannula inserted in the second intercostal space in the midclavicular line. An intercostal drain is then inserted after decompression. Often emergency treatment must be based on a clinical diagnosis without radiological confirmation, because of life threatening haemodynamic compromise. Radiographic features suggesting tension pneumothorax include cardiome diastolic shift away from the affected side and, in some cases, inversion of the hemidiaphragm and widening of intercostal spaces from the increased pressure within the affected hemithorax.

How is pneumothorax diagnosed?
Pneumothorax may be asymptomatic and diagnosed radiologically or may be suspected on the basis of typical clinical features. The most common symptoms are chest pain and breathlessness, characteristically with an acute onset, although these may be subtle or even absent. Patients with secondary pneumothorax tend to have more symptoms than those with primary pneumothorax as a result of coexistent lung disease. Clinical signs of pneumothorax include a reduction in lung expansion, a hyper-resonant percussion note, and diminished breath sounds on the affected side. The presence of hypotension and tachycardia may indicate tension pneumothorax.

SUMMARY POINTS

- Primary spontaneous pneumothorax is associated with smoking but defined as occurring in the absence of known lung disease
- Secondary spontaneous pneumothorax occurs in the presence of known lung disease and is associated with increased symptoms, morbidity, and rates of tension pneumothorax
- Immediate recognition and management of tension pneumothorax is required to prevent death
- Smoking increases the risk of pneumothorax and rates of recurrence, and smoking cessation is strongly advised
- Surgical intervention is warranted for patients with recurrent pneumothorax as the risk of further recurrence is high

SOURCES AND SELECTION CRITERIA

We searched the Cochrane database of systematic reviews for articles related to pneumothorax. We searched Medline using the search term “pneumothorax” appearing in relevant study types (clinical trials, literature reviews, and meta-analyses) as well as in recent conference proceedings. We limited studies to those in adults. We focused on randomised controlled trials, systematic reviews, and meta-analyses, and where possible used recent studies. The most up to date versions of relevant guidelines (British Thoracic Society, American College of Chest Physicians) were reviewed, as was information from clinical evidence.bmj.com and uptodate.com.
In most patients, the diagnosis will be confirmed on a standard, inspiratory chest radiograph. Routine expiratory films are not recommended routinely as they do not improve diagnostic yield, contrary to historical recommendations. The hallmark of a pneumothorax on a radiograph is a white visceral pleural line separated from the parietal pleura and chest wall by a collection of gas, resulting in a loss of lung markings in this space (fig 1).

Features of pneumothorax may be more subtle on supine radiographs, with more air needed within the pneumothorax to confidently make a diagnosis. The deep sulcus sign, caused by air collecting in the costophrenic sulcus, apparently deepening it, may indicate pneumothorax on a supine radiograph.

Computed tomography provides sensitive and specific imaging for pneumothorax and is particularly useful for complex disease processes, including pneumothoraces that are loculated as a result of areas of lung remaining adherent to parietal pleura, as well as facilitating radiologically guided drain insertion in difficult cases. Additionally, computed tomography is useful in distinguishing a pneumothorax from large bullae, which may occur in severe emphysema and can mimic the appearance of pneumothorax due to the absence of lung markings within a bulla. Typically, on chest radiographs bullae are indicated by a concave appearance, whereas a pneumothorax is suggested by a visceral pleural line running parallel to the chest wall; however, this distinction may be made clearly with computed tomography, potentially avoiding the serious complication of inserting a drain into lung parenchyma.

What predisposes to pneumothorax?

Primary spontaneous pneumothorax

The most important risk factor contributing to risk of primary pneumothorax is tobacco smoking. A retrospective study over 10 years conducted in Stockholm assessed the smoking habits of 138 patients with primary pneumothorax and compared their rates of smoking with a contemporary random sample of over 15,000 people from the same geographical area. Within this study, 88% of the patients with primary pneumothorax smoked. Compared with non-smokers, the relative risk of a first pneumothorax is increased by ninefold in women who smoke and by 22-fold in men who smoke. In addition, this study found a striking dose-response relation between number of cigarettes smoked a day and risk of pneumothorax. Cannabis smoking is associated with pneumothorax, an effect that may be attributed to both parenchymal damage from smoke and the longer breath-holds or Valsalva manoeuvres that may be associated with smoking cannabis.

The risk of primary pneumothorax is greater in tall men, which has led to the hypothesis that a greater alveolar stretch at the lung apex in tall men contributes to the increased risk.

Secondary spontaneous pneumothorax

Chronic obstructive pulmonary disease is the most common lung disease causing secondary pneumothorax, accounting for around 57% of cases.

Fig 1 Large right sided secondary pneumothorax in patient with severe chronic obstructive pulmonary disease and acute dyspnoea. White arrows indicate visceral pleura surrounding collapsed lung.
Fig 2 Initial management of pneumothorax. Adapted from British Thoracic Society guidelines, MacDuff et al. 

Some patients with a large primary pneumothorax but minimal symptoms may also be appropriate for conservative management.

What are the treatment options?

What predicts recurrence of pneumothorax?

Primary spontaneous pneumothorax

Smoking cessation is the only proved modifiable risk factor for recurrence of primary pneumothorax. In a retrospective study of patients with primary pneumothorax, including 99 smokers, the absolute risk of recurrent pneumothorax in the four year follow-up period was 40% in those who stopped smoking compared with 70% in those who continued to smoke. Recurrence of primary pneumothorax is also associated with increased height in men and is significantly reduced by open surgery or video assisted thoracic surgery.

Secondary spontaneous pneumothorax

Patients with pre-existing lung disease are more likely to experience a recurrent pneumothorax than those with primary pneumothorax. In a retrospective study of 182 patients, of whom around half had chemical pleurodesis, recurrence rates at one year were 15.8% for primary pneumothorax and 31.2% for secondary pneumothorax. Rates of recurrence of secondary pneumothorax are noticeably lowered by thoracic surgery: after video assisted thoracic surgery or axillary minithoracotomy, recurrence rates of around 3% were reported in a study with a mean follow-up period of 30 months, whereas a separate study, with a similar duration of follow-up, reported recurrence rates of 43% in a control group of 86 patients with secondary pneumothorax.

What is the goal of management?

The goal of acute treatment in pneumothorax is to exclude a tension pneumothorax and to relieve any dyspnoea. These goals are reflected by the different treatment algorithms in patients with primary or secondary pneumothorax, as patients with the latter are more likely to be symptomatic and more prone to associated cardiopulmonary compromise, in view of pre-existing disease. In contrast, patients with primary pneumothorax are often asymptomatic and tension pneumothorax is uncommon in this population.

Early studies evaluating treatment of pneumothorax focused on radiological resolution rather than patient centred outcomes, and this may have previously resulted in guidelines focused on intervention to remove air from the pleural space. Goals of treatment in pneumothorax are to exclude tension and reduce early morbidity and symptoms associated with pneumothorax, to limit inpatient management where possible, to reduce the risk of recurrence, and to identify patients who would benefit from a definitive surgical procedure.

What predicts recurrence of pneumothorax?

What are the treatment options?

What is the goal of management?
A randomised controlled trial of 56 patients assessed manual aspiration against intercostal drain insertion in patients with large primary pneumothorax. Success and recurrence rates did not differ between the groups and manual aspiration was associated with significantly shorter hospital stays, suggesting that this strategy is appropriate in this group. An earlier Cochrane review, limited by the inclusion of only a single randomised controlled trial, also suggested that aspiration was no different from chest drain insertion in terms of early success or success at one year, and was associated with a reduction in the number of patients admitted to hospital.  

Secondary spontaneous pneumothorax

Management of secondary pneumothorax tends to involve a more interventional approach because of the associated increased morbidity, symptoms, and cardiorespiratory compromise. In reflection of this, both American College of Chest Physicians and British Thoracic Society guidelines recommend admission for all episodes of secondary pneumothorax. Oxygen is indicated, but some caution may be required for patients at risk of carbon dioxide retention. Although most patients may ultimately require an intercostal drain, the British guidelines recommend attempting aspiration for asymptomatic secondary pneumothorax measuring 1-2 cm at the hilum, whereas the American consensus statement suggests that this is not appropriate.  

Air leakage in secondary pneumothorax is less likely to settle spontaneously than in primary pneumothorax and patients with secondary pneumothorax have a longer average length of stay than those with primary pneumothorax: more than 10 days in some series. Discussion with a thoracic surgeon is advised after 48 hours of persistent air leakage, offering an individualised approach to surgical management dependent on risks of recurrence and surgical morbidity. Some patients are unfit for a definitive surgical procedure or a less invasive management strategy.

Suction

The use of suction through chest drains has been employed in patients with persistent air leak or incomplete lung re-expansion in whom the rate of air leakage from the lung may be greater than the removal of air from the pleural space through the drain. This is utilised to increase the air flow out through the drain in the hope that if the visceral and parietal pleura can be apposed then the air flow out through the drain in the hope that if the visceral pleura may heal more readily. A small randomised study of 23 patients found no significant differences in rates of lung re-expansion and duration of hospital stay between suction and no suction. British Thoracic Society guidelines recommend that suction is not routinely employed in the management of pneumothorax but can be used if the lung fails to re-expand; a pressure of −10 to −20 cm H2O as part of a high-volume low-pressure system is the recommended method. Such a system should minimise the risk of increasing air leak and “air-stealing”—a process by which a large volume of each breath is entrained out of the chest through the drain. The early application of suction after drainage of a pneumothorax should be avoided because of an increased risk of re-expansion pulmonary oedema precipitated by the rapid re-inflation of the collapsed lung.

Surgery

Axillary minithoracotomy and video assisted thoracic surgery are both used for the treatment of recurrent pneumothorax. A recent randomised controlled trial of 66 patients with primary or secondary pneumothorax allocated to minithoracotomy or to video assisted thoracic surgery showed equivalent recurrence rates (2.7% and 3%, respectively) and postoperative pain. Compared with minithoracotomy, video assisted thoracic surgery was associated with higher patient satisfaction (assessed by use of the ipsilateral arm postoperatively) and return to activity, albeit at the expense of a longer procedure time.

Pleurodesis

Pleurodesis is a procedure that precipitates an inflammatory process leading to the adherence of parietal and visceral pleura, thereby obliterating the pleural space. This can be achieved through instillation of an agent such as talc or tetracycline derivatives through a chest drain (medical pleurodesis) or by mechanical abrasion of the pleura or instillation of a suitable agent during an operation (surgical pleurodesis). Because of the inflammatory nature of pleurodesis, it can be painful and requires the application of local anaesthesia into the pleural space as well as adequate analgesia.

A randomised controlled trial of 214 patients with primary pneumothorax in Taiwan assessed the effect of minocycline pleurodesis on recurrence of pneumothorax at one year. All the patients had pigtail catheters for aspiration of their pneumothorax and were randomised to minocycline pleurodesis or to no pleurodesis. Recurrence rates were significantly lower (P=0.003) in the minocycline pleurodesis group (29.2%) compared with the control group (49.1%). This method of treatment, however, typically necessitated a two day hospital stay, and the rate of recurrence in the control group was higher than that reported in other studies (33% at one year in one study). An earlier smaller randomised study including participants with primary and secondary pneumothorax compared simple drainage with tetracycline or talc pleurodesis and found that the rate of recurrence over a mean follow-up period of 4.6 years was only 8% in the talc pleurodesis group but 36% in the simple drainage group. British Thoracic Society guidelines suggest that chemical pleurodesis should be considered only in patients with an ongoing air leak who are not fit for surgical intervention, rather than as a primary treatment, in view of the significantly lower recurrence rates (around 3%) after surgery.

What advice do patients need after a pneumothorax?

Given the considerable recurrence rate for pneumothorax it is important that patients are advised of the symptoms that may indicate recurrence and the need to seek medical advice if this occurs.

British Thoracic Society guidelines suggest that all patients with a pneumothorax are followed up by a respiratory physician around 2-4 weeks after the initial episode to ensure resolution and to identify and treat underlying lung disease. Patients can be advised to return to work and normal activity after resolution of symptoms, although extreme exertion and contact sports should be delayed for longer and until full radiological resolution. Smoking cessation significantly reduces the recurrence rate in patients after an initial primary pneumothorax, with a relative risk reduction of over 40%. Therefore patients should be made aware of this and provided with support to successfully stop smoking. Aside from medical intervention,
smoking is the only modifiable risk factor predicting recurrence. Unfortunately, smoking cessation rates seem to be low after pneumothorax; more than 80% of patients in a retrospective study of 142 patients with primary pneumothorax continued to smoke one year after the episode.²⁵

Diving
British Thoracic Society guidelines advise that scuba diving should be avoided indefinitely after a pneumothorax unless a definitive procedure such as surgical pleurectomy has been performed.²⁴ This is because of the risk of recurrent pneumothorax underwater, the expansion of a pneumothorax that may develop during ascent, and the risk of resultant tension pneumothorax. For professional divers a decision to offer definitive surgical management after the first pneumothorax episode may allow safe reintroduction to diving.

Air travel
Air travel should not increase the risk of pneumothorax, but the consequences of a pneumothorax while airborne are such that patients should not travel on commercial flights with an undrained pneumothorax, and air travel should be delayed until after definitive intervention or until resolution has been confirmed radiologically.²⁶ The chances of recurrent pneumothorax and the degree to which patients would tolerate a recurrence will influence the decision on whether the risk of air travel is acceptable to an individual. The UK civil aviation authority suggests that it is safe to travel two weeks after successful drainage of a pneumothorax.

What new treatments can be expected?
Conservative treatment
British Thoracic Society guidelines recommend that conservative management should be considered in patients with a small pneumothorax (≤2 cm to lung edge at level of hilum) who are not breathless and acknowledge that it may be appropriate in patients with a large pneumothorax and minimal symptoms. An Australian randomised controlled trial is currently recruiting patients with larger primary pneumothorax to compare conservative management (observation then discharge if clinically stable) with standard management (aspiration and chest drain insertion if unsuccessful) on lung re-expansion at eight weeks as well as the effect on symptoms, complications, and recurrence.²⁷

Quantification of air leak
Digital thoracic drainage systems allow a quantification of air leak that is not possible with a conventional underwater seal. These systems have been studied predominantly in patients with air leakage after thoracic surgery, but they may allow earlier stratification in pneumothorax, distinguishing those patients who are likely to have a persistent air leak from those whose air leak will settle with continued intercostal tube drainage. Endobronchial valves
Endobronchial valves have been utilised as a nonsurgical means of achieving a reduction in lung volume in emphysema and have also been studied as a treatment for persistent air leak in pneumothorax. These one-way valves may be inserted during a bronchoscopy, and when placed in segmental or subsegmental bronchi allow collapse of the distal lung and reduction in air leak while allowing drainage of secretions from distal airways. Endobronchial valves have been studied in 40 patients with varying causes of ongoing air leak, 25 of whom had spontaneous pneumothorax. Of the total, 93% (n=37) had a reduction or resolution in air leak, with 48% (n=19) achieving a complete resolution of leak.²⁸ This technique may allow a non-surgical method of managing patients who do not respond to conventional treatment, and prospective trials may help elucidate its role.

Blood patch
The effect of intrapleural injection of autologous blood was assessed in a small randomised controlled trial of 44 patients with advanced chronic obstructive pulmonary disease, secondary pneumothorax, and a persistent air leak after seven days of intercostal tube drainage.²⁹ This intervention was associated with a statistically significant reduction in ongoing air leak at 13 days. The air leak stopped in 9% (n=1) of those administered placebo and 73% (n=16) administered 1-2 mL/kg of blood, with greater success rates seen in those with a smaller air leak. Fourteen per cent of patients who were administered this dose of blood developed a low grade fever, which in all cases settled quickly with antibiotics. This study suggests that this technique may be useful as an alternative to chemical pleurodesis in patients with a significant risk from surgery.³⁰

Ambulatory treatment
Heimlich valves are one-way flutter valves that may be attached to an intercostal drain in place of an underwater seal. They offer an outpatient treatment option for the management of pneumothorax, which may have an increasing role in the future. A randomised controlled trial of 48 patients with primary pneumothorax presenting to emergency departments compared Heimlich valves with needle aspiration and detected non-significantly lower rates of admission of 44% (n=11) in the valve group compared with 61% (n=14) in the needle aspiration group. At first outpatient review, full re-expansion of the lung occurred in 24% (n=6) of participants in the valve group compared with only 4% (n=1) in the needle aspiration group. Both procedures appeared safe, were well tolerated, and the intercostal drain was removed at a mean of 3.5 days in participants in the valve group.³¹

A subsequent systematic review (n=1235 cases) assessed available evidence for the use of Heimlich valves.³² Despite being limited by a large proportion of unrandomised data with potential sources of bias, the review suggested an overall success rate of 85.8% with Heimlich valves, with successful treatment as an outpatient in 77.9% of cases. This treatment may offer benefits related to comfort and the avoidance of admissions with acceptable complication rates of 1.7%.³³ A larger well designed randomised controlled trial evaluating the use of Heimlich valves is required to evaluate the utility of this device.
After pneumothorax, air travel should be delayed until after definitive intervention or until resolution has been confirmed radiologically—the UK civil aviation authority recommends delaying air travel until two weeks after resolution.

TIPS FOR NON-SPECIALISTS

- The diagnosis can usually be made on chest radiographs, but computed tomography is sometimes required.
- The presence of haemodynamic compromise with pneumothorax may indicate tension pneumothorax, which requires urgent decompression with a cannula through the second intercostal space in the midclavicular line.
- Smoking cessation reduces the risk of recurrence of primary spontaneous pneumothorax.
- After pneumothorax, air travel should be delayed until after definitive intervention or until resolution has been confirmed radiologically—the UK civil aviation authority recommends delaying air travel until two weeks after resolution.

Diagnosis and management of pulmonary embolism

S Takach Lapner, research fellow and haematologist, C Kearon, professor of medicine

Pulmonary embolism is one manifestation of venous thromboembolism, the other being deep vein thrombosis. Pulmonary embolism occurs when a deep vein thrombosis breaks free, passes through the right side of the heart, and lodges in the pulmonary arteries. About 90% of pulmonary emboli come from the legs, with most involving the proximal (popliteal or more central) veins. Prevention of pulmonary embolism therefore requires both prevention of venous thromboembolism and effective treatment of deep vein thrombosis when it occurs. There is a wealth of high quality individual studies and meta-analyses to guide the diagnosis and treatment of pulmonary embolism, and we provide an overview and synthesis of that evidence in this review.

Why is pulmonary embolism important?
Symptomatic venous thromboembolism occurs in 1–2 per 1000 adults each year, with about a third presenting with pulmonary embolism.1 2 Pulmonary embolism is the most common cause of vascular death after myocardial infarction and stroke, and the leading preventable cause of death in hospital patients.3 About 10% or more of cases of symptomatic pulmonary embolism are thought to be rapidly fatal, and another 5% of patients die after starting treatment. About a third of patients are left with some residual symptoms, and 2% develop thromboembolic pulmonary hypertension due to unresolved pulmonary embolism.1

Who is at risk?
Presentation of venous thromboembolism as pulmonary embolism rather than deep vein thrombosis is more common in elderly people and in those with cardiorespiratory disease, and less common in those with factor V Leiden. Three quarters of venous thromboembolisms are first events, while a quarter are recurrences, mainly after stopping treatment. Incidence doubles with each decade of age, and is about one per 1000 at 60 years. First episodes of venous thromboembolism occur with similar frequency in men and women, except for an increase in younger women associated with oestrogen therapy. Compared with white people, the incidence of venous thromboembolism is about 20% higher with African ethnicity and 33% lower with Asian ethnicity.

Virchow identified hypercoagulability, vessel wall injury, and stasis as the pathogenic triad for thrombosis (box 1). About 25% of patients with venous thromboembolism have no apparent provoking risk factor (“unprovoked” or “idiopathic” venous thromboembolism), 50% have a temporary provoking risk factor such as recent surgery or oestrogen therapy, and 25% have cancer.4 Half of venous thromboembolism episodes are associated with hospitalisation, and about half of these are in surgical patients and half occur after hospital discharge. Therefore, preventive measures in hospitalised patients who are at high risk have the potential to markedly reduce pulmonary embolism.

How does pulmonary embolism present?
The symptoms and signs are non-specific and vary with the extent of pulmonary embolism and underlying cardiopulmonary impairment. Extensive pulmonary embolism may present with syncope, due to acute lowering of cardiac output, and patients may be found to have hypotension, evidence of poor perfusion (such as confusion), and elevated jugular venous pressure. Breathlessness occurs in most patients. Pleuritic chest pain is caused by pulmonary infarction, which occurs more often with non-massive pulmonary embolism and may be associated with haemoptysis. Although symptoms are usually present for days or weeks, they may be longstanding. Less than a quarter of patients have symptoms or signs of deep vein thrombosis, even though deep vein thrombosis is present in most patients with pulmonary embolism. Unexplained tachycardia, tachypnoea, or low arterial oxygen saturation may also suggest pulmonary embolism.

With the widespread use of computed tomography, particularly for the assessment of cancer progression, diagnosis of incidental pulmonary embolism has become increasingly common. Incidental pulmonary embolism was reported in 2.6% of thoracic scans in one meta-analysis, with higher prevalence among hospitalised and cancer patients.4 In retrospect, many of these patients had symptoms such as fatigue or breathlessness.

How is pulmonary embolism diagnosed?
Before describing the specific test results, or combinations of test results, that “rule in” and “rule out” pulmonary embolism, we will first quantify the level of diagnostic certainty that is required for each of these goals. The primary goal of diagnostic testing for pulmonary embolism...
is to identify patients who would benefit from treatment. We suggest that a pulmonary embolism probability of $\geq 85\%$ is the threshold that “rules in” pulmonary embolism and justifies anticoagulant therapy; this corresponds to a moderate or high clinical suspicion for pulmonary embolism and a “high probability” ventilation-perfusion lung scan. Conversely, the threshold that “rules out” pulmonary embolism and justifies withholding anticoagulant therapy is a $\leq 2\%$ probability of progressive venous thromboembolism in the next three months. We emphasise that the threshold for withholding anticoagulant therapy focuses on the risk of continuing or progressive symptoms from pulmonary embolism, or of a new episode of venous thromboembolism (that is, progressive thrombosis) during follow-up, rather than the probability that pulmonary embolism is present and has been missed; it is acceptable not to treat a patient with test results possibly associated with pulmonary embolism provided we are confident, based on the findings of previous prospective studies, that patients with those test results have a very low risk for progressive venous thromboembolism. If the probability of pulmonary embolism lies between these two thresholds the patient requires further testing. If, despite further testing, findings remain non-diagnostic, the options are to (a) withhold treatment while performing serial ultrasound imaging of the proximal deep veins of the leg over a two week period and to treat only if deep vein thrombosis is detected (usually the preferred option); or (b) treat despite a pulmonary embolism probability of $\leq 85\%$ (less preferable).

Clinical pre-test probability

Diagnosis of pulmonary embolism starts with an assessment of clinical pre-test probability. This is based on assessment of whether symptoms and signs are typical for pulmonary embolism, if there are risk factors for pulmonary embolism, if pulmonary embolism is thought to be the most likely diagnosis, and if there is evidence of deep vein thrombosis.

*Combinations of factors have at least an additive effect on the risk of venous thromboembolism

CPPT is facilitated by use of a clinical prediction rule, of which the Wells score (table 1) is most widely used and extensively validated. Although CPPT alone cannot diagnose pulmonary embolism, and generally does not exclude pulmonary embolism, it guides the selection of diagnostic tests (for example, a confirmatory test with high CPPT, an exclusionary test with low CPPT) and may be diagnostic in combination with these test results (box 2). Every patient for whom pulmonary embolism is initially considered does not need to be tested for pulmonary embolism; a convincing alternative diagnosis may subsequently be found.

D-dimer testing

D-dimer is formed when cross linked fibrin is broken down by plasmin. Levels are almost always increased in venous thromboembolism, and consequently a normal D-dimer level helps to rule out pulmonary embolism (that is, it has a high negative predictive value). However, because D-dimer levels are commonly increased by other conditions, an abnormal result has low positive predictive value for pulmonary embolism. D-dimer tests vary in terms of the measurement method and the D-dimer level that is used to categorise a test as positive or negative; consequently, negative predictive value differs among D-dimer tests, and this influences how a negative D-dimer result is used to rule out pulmonary embolism in combination with CPPT or other test results. D-dimer tests can be divided into those that are highly, or only moderately, sensitive for venous thromboembolism.

Highly sensitive tests have sensitivity $\geq 95\%$, but specificity is only about $40\%$ in outpatients (lower in inpatients, see below). A negative highly sensitive test has very high negative predictive value and therefore rules out pulmonary embolism in patients with low or moderate CPPT (box 2); however, a negative test is obtained in only about $30\%$ of outpatients because of the low specificity.

Moderately sensitive tests have a sensitivity of $80\%-94\%$, and a specificity of up to $70\%$ in outpatients. A negative test has lower negative predictive value than a very sensitive D-dimer test and therefore rules out pulmonary embolism only in patients with low CPPT (box 2); however, most outpatients with low CPPT who do not have pulmonary embolism have a negative test, which increases the value of testing.

Specificity of D-dimer testing decreases with age, pregnancy, inflammatory conditions, cancer, trauma, and recent surgery. If it is very probable that a patient will have a positive D-dimer test in the absence of pulmonary embolism, such as after major surgery, D-dimer testing should not be performed. It is also of limited value in patients with high CPPT because about half will have a positive test due to pulmonary embolism and, if a negative test is obtained, its negative predictive value is reduced by the high prevalence of disease. D-dimer testing should not be ordered to “screen out” pulmonary embolism in patients who have yet to be evaluated clinically because the high frequency of false positive results will increase, rather than decrease, the need for additional testing.

Computed tomographic pulmonary angiography

Computed tomographic (CT) pulmonary angiography, which outlines thrombi in the pulmonary arteries with intravenous contrast medium, has become the primary diagnostic test for pulmonary embolism. Its positive predictive value varies with the extent of pulmonary embolism and CPPT: the positive predictive value is $(a) \ 97\%$ with main or lobar, $68\%$...
with segmental, but only 25% with isolated subsegmental pulmonary artery abnormalities, and (b) 96% with high CPTP, 92% with moderate CPTP, but only 58% with low CPTP (box 2). Management studies have established that it is safe to withhold anticoagulant therapy in patients with a good quality negative CT pulmonary angiogram, with only about 1% of such patients returning with progressive venous thromboembolism during three months of follow-up (box 2).

Isolated subsegmental abnormalities, which are reported in 10–20% of CT pulmonary angiograms, may be due to pulmonary embolism that is causing symptoms or incidental pulmonary embolism that is not responsible for the patient’s symptoms (such as after knee replacement surgery), or may be false positive findings. Consequently, it is uncertain if patients with these findings should be treated (box 2). We treat patients with isolated subsegmental abnormalities if there is persuasive evidence for pulmonary embolism (clear, usually multiple, defects on CT pulmonary angiography; moderate or high CPTP) and the risk of bleeding is not high, and we conduct serial ultrasound scans of the deep veins of the legs over two weeks in those who we do not treat, similar to how we manage patients with non-diagnostic ventilation-perfusion scans (see below). Less than 10% of CT pulmonary angiograms are technically inadequate.

CT pulmonary angiography can lead to contrast induced nephropathy and is associated with substantial radiation exposure. Its use should therefore be minimised, particularly in women under the age of 40 because of the associated increased risk of breast cancer.

**Ventilation-perfusion lung scanning**

Ventilation-perfusion lung scanning has largely been supplanted by CT pulmonary angiography. A “high probability scan,” in which there is ≥1.5 segmental perfusion defects with normal ventilation (“ventilation-perfusion mismatch”), is associated with a prevalence of pulmonary embolism of ≥85% and is seen in about half of patients with pulmonary embolism (box 2). A normal perfusion scan rules out pulmonary embolism, but is found in only 25% of patients. More than half of patients, therefore, have a non-diagnostic scan and require further testing. CT pulmonary angiography can then be performed, but ventilation-perfusion scanning is often done when CT pulmonary angiography is contraindicated (for example, with renal insufficiency). Consequently, it is usually preferable to do venous ultrasound scans of the proximal deep veins of both legs on the day of presentation and twice during the next two weeks, and to treat patients only if deep vein thrombosis is detected. The specificity of ventilation-perfusion scanning is lower if there is respiratory disease, and higher in younger patients.

**Score interpretation**

- **High probability**
  - Score 2.5–6.0
  - 10% of patients
  - Prevalence of pulmonary embolism 60%

- **Moderate probability**
  - Score 6.5–9.0
  - 30% of patients
  - Prevalence of pulmonary embolism 25%

- **Low probability**
  - Score ≥9.5
  - 60% of patients
  - Prevalence of pulmonary embolism 5%

* A score of ≥4.5 (moderate and high probability groups combined) has been termed “pulmonary embolism likely.” This group makes up about 40% of patients and has a prevalence of pulmonary embolism of about 35%.

**BOX 2: TEST RESULTS THAT CONFIRM OR EXCLUDE PULMONARY EMBOLISM (ADAPTED FROM KEARON)**

**Diagnostic for pulmonary embolism (≥85% probability of pulmonary embolism)**

- Computed tomography (CT) pulmonary angiogram:
  - Intraluminal filling defect in a lobar or main pulmonary artery
  - Intraluminal filling defect in a segmental pulmonary artery and moderate or high CPTP
  - Ventilation-perfusion scan: High probability scan* and moderate or high CPTP
  - Positive diagnostic test for deep vein thrombosis (with a non-diagnostic ventilation-perfusion scan or CT pulmonary angiogram)

**Excludes pulmonary embolism (≤52% probability of progressive venous thromboembolism during 3 months’ follow-up)**

- CT pulmonary angiogram: Normal
- Perfusion scan: Normal
- D-dimer test:
  - Negative test which has high sensitivity (>95%) and low or moderate CPTP
  - Negative test which has moderately high sensitivity (>85%) and low CPTP
  - Non-diagnostic ventilation-perfusion scan or suboptimal CT pulmonary angiogram and normal venous ultrasound of the proximal veins and
  - Low CPTP or
  - Negative D-dimer test which has moderately high sensitivity (>285%) or
  - Normal repeat venous ultrasound scans of the proximal veins after 7 and 14 days

*Presence of two large (each ≥0.75 segments) perfusion defects with normal ventilation.
†Patients should be told there is still a small chance that pulmonary embolism is present and instructed to return for further evaluation if symptoms persist or deteriorate.

**Diagnosis of pulmonary embolism in pregnancy**

Diagnosis of pulmonary embolism is similar in pregnant and non-pregnant patients, although there are some differences, and many diagnostic strategies have not been well validated in pregnant women. Although the specificity of D-dimer testing decreases in later pregnancy, it is expected to retain most of its negative predictive value. Ultrasound scans of the leg veins, particularly if there are leg symptoms, may identify deep vein thrombosis. Ventilation-perfusion scanning with a lower radiation dose and longer imaging period for the perfusion component, or CT pulmonary angiography modified for physiological changes in pregnancy, can be used. Ventilation-perfusion scanning is probably associated with higher fetal radiation that CT pulmonary angiography, but this is still below the level considered harmful. CT pulmonary angiography is associated with much higher maternal radiation. Non-diagnostic ventilation-perfusion scans are also much less common during pregnancy (young patients without comorbidity) than in the general population. For these reasons, if imaging is necessary, we usually prefer ventilation-perfusion scanning to CT pulmonary angiography in pregnant patients, and prefer to do serial ultrasound testing rather than CT pulmonary angiography in patients with non-diagnostic ventilation-perfusion scans. CT pulmonary angiography is preferred to ventilation-perfusion scanning in sicker patients and particularly if there is haemodynamic instability or if the results of chest radiography suggest that a ventilation-perfusion scan is likely to be non-diagnostic.

Isolated iliac deep vein thrombosis is more common in pregnant patients, which, if the iliac veins are not part of the initial and follow-up examinations, may undermine the role of serial venous ultrasonography.
How is pulmonary embolism treated?

Anticoagulant therapy before diagnostic testing

This decision depends on the probability that pulmonary embolism is present, how soon diagnostic testing can be performed, how sick the patient is, and the patient’s risk of bleeding. A pragmatic approach is to start anticoagulant therapy if (a) CPTP is high, (b) CPTP is moderate and testing will not be completed within four hours, or (c) CPTP is low and testing will be delayed for over 24 hours.17

Treat patients with incidental pulmonary embolism

Incidental pulmonary embolism, detected on a CT scan that has been done for another reason, is often reported after an outpatient has left the hospital. If it would be difficult for patients to return the same evening, it is usually reasonable to defer further evaluation and treatment until the next day because, if pulmonary embolism is confirmed, it has usually been present for some time.17 The decision whether to treat long term will be influenced by the certainty that pulmonary embolism is present (addition diagnostic testing, such as dedicated CT pulmonary angiography, may be required), whether the abnormality has gone unnoticed on previous CT scans, and the patient’s risk of bleeding. However, because incidental pulmonary embolism seems to carry a similar risk of recurrence and poor long term prognosis as symptomatic pulmonary embolism, we treat most the same way as symptomatic episodes.

When are thrombolytic therapy and mechanical thrombus removal used?

Active removal of thrombus is mostly reserved for the roughly 5% of patients with pulmonary embolism who have hypotension (systolic blood pressure <90 mm Hg; usually with other features of shock).17 18 Systemic thrombolytic therapy is most commonly used, often as 100 mg of tissue plasminogen activator given as a two hour infusion.17 Alternatively, if expertise is available, thrombus removal may be achieved by infusion of lower doses of thrombolytic drug directly into the thrombus, by catheter based fragmentation and aspiration of thrombus, by use of these two modalities together, or by surgical embolectomy.17 18 These techniques may be preferred if there is a high risk of bleeding,17 a poor response to systemic thrombolyis, or concern that the patient will die before systemic thrombolytic therapy has a chance to work.17 Surgical embolectomy is indicated if there is impending paradoxical embolism, with thrombus present in a septal defect.

While there is strong evidence from randomised trials that systemic thrombolysis accelerates resolution of pulmonary embolism, its ability to save lives or reduce long term cardiopulmonary impairment remains uncertain.19 Fewer than 800 patients have been included in trials that have randomised patients with acute pulmonary embolism to receive or not receive thrombolytic therapy, and these trials were usually not designed to assess clinical outcomes, did not follow up patients to assess long term disability, and had other important methodological limitations that undermine confidence in their findings.4 19 Systemic thrombolytic therapy, however, is known to markedly increase risk of bleeding, and particularly intracranial bleeds.

Use of thrombus removal interventions in patients with pulmonary embolism and hypotension is based on the expectation that these patients, who otherwise are expected to have a mortality of up to 30%, will derive net benefit.1 17 Right ventricular dysfunction on echocardiography and elevated biomarkers of right ventricular injury are predictive of short term mortality from pulmonary embolism; two ongoing large trials are testing if, in the absence of hypotension, patients with these findings benefit from systemic thrombolytic therapy (NCT00659743; NCT00680628).

VTE= venous thromboembolism. DVT=deep vein thrombosis. PE=pulmonary embolism.

†Treatment with a vitamin K antagonist (VKA) or low molecular weight heparin (LMWH) are currently considered first line therapy. VKA therapy is suggested in preference to LMWH in patients without cancer (anosial injection, less costly). LMWH is preferred in patients with cancer (more effective, lasting and reversal more flexible) if there is severe thrombocytopenia or invasive procedures are required, VKA is difficult to control in sicker patients). The choice between VKA and LMWH is also sensitive to patient preference. New oral anticoagulants (such as rivaroxaban, dabigatran) are considered second line therapy as they are not yet widely available or approved for extended therapy of VTE, and there is limited post-marketing experience with these agents.17 18

‡These techniques may be preferred if there is a high risk of bleeding,17 a poor response to systemic thrombolysis, or concern that the patient will die before systemic thrombolytic therapy has a chance to work.17 Surgical embolectomy is indicated if there is impending paradoxical embolism, with thrombus present in a septal defect.

Anticoagulant therapy

Anticoagulant therapy can be divided into two overlapping phases.17 20 The first is treatment of the presenting episode of pulmonary embolism, which takes about three months. The second, which is optional, is extended therapy designed to prevent new episodes of venous thromboembolism.

Standard initial therapy is with subcutaneous low molecular weight heparin, fondaparinux, or unfractionated heparin, or intravenous unfractionated heparin.17 There is no strong evidence that any one method is superior. Subcutaneous low molecular weight heparin and fondaparinux do not require intravenous infusion or laboratory monitoring, whereas intravenous unfractionated heparin is preferred if there is shock, severe renal impairment (low molecular weight heparin and fondaparinux are renally excreted), thrombolytic therapy is being considered, or it may be necessary to reverse anticoagulation rapidly. These treatments should be overlapped with a vitamin K antagonist (such as warfarin) and stopped after a minimum of five days provided the international normalised ratio (INR) has been above 2.0 for at least a day.

Alternatively, low molecular weight heparin can be continued long term, a treatment strategy that is generally preferred in patients with cancer associated pulmonary embolism because of superior efficacy of low molecular weight heparin, difficulty in controlling vitamin K antagonist therapy, and greater compatibility of low molecular weight heparin with chemotherapy and the need for invasive procedures.17 20 Long term low molecular weight heparin is also used to treat venous thromboembolism during pregnancy because vitamin K antagonists are teratogenic. Observational studies and a recent randomised trial have shown that, with appropriate selection (less acutely ill, good social supports, patient preference), about half of outpatients with acute pulmonary embolism can be treated at home.4 21

The new oral anticoagulants rivaroxaban and dabigatran (apixaban is at an earlier stage of assessment in the treatment of venous thromboembolism) are as effective
as conventional anticoagulant therapy, do not require laboratory monitoring, and are associated with a lower risk of intracranial bleeding but a higher risk of gastrointestinal bleeding.\textsuperscript{11} \textsuperscript{16} \textsuperscript{37} \textsuperscript{39} \textsuperscript{40} Dabigatran is preceded by heparin therapy, whereas rivaroxaban does not require initial heparin therapy but requires a higher dose for the first three weeks of treatment. Both are contraindicated if there is severe renal impairment and are contraindicated or must be used cautiously with some drugs, and there is little experience of using them to treat venous thromboembolism in patients with advanced cancer or receiving cancer chemotherapy. The decision to use one of these drugs for the acute or long term treatment of venous thromboembolism is also influenced by local availability and licensing, whether their cost is covered by state or private insurance plans, and patient and physician satisfaction with current therapy. Because they are emerging therapies, these factors differ among jurisdictions and are rapidly changing.

**How long should anticoagulant therapy be continued?**

When the presenting episode of pulmonary embolism has been effectively treated, there is the option of continuing anticoagulants indefinitely to prevent new episodes of venous thromboembolism. Extended therapy reduces the risk of recurrent venous thromboembolism by over 90\%, but increases the risk of bleeding twofold to threefold.\textsuperscript{17} If anticoagulant treatments are extended and then stopped the risk of recurrent venous thromboembolism is similar to that if they had been stopped at three months, with the highest risk occurring in the first six months after stopping.\textsuperscript{18} \textsuperscript{31} The risk of recurrent venous thromboembolism is similar after a pulmonary embolism or a proximal deep vein thrombosis, but the recurrent episode is about three times as likely to be a pulmonary embolism after an initial pulmonary embolism, so is more likely to be fatal.\textsuperscript{18} The decision to treat indefinitely therefore depends on balancing the increased risk of recurrence with stopping therapy against the increased risk of bleeding with continued therapy, while also considering patient preference and associated costs.

Most patients with active cancer or a second unprovoked venous thromboembolism should receive extended therapy because of a high risk of recurrence (table 2).\textsuperscript{27} Most patients with pulmonary embolism associated with a reversible provoking risk factor, such as surgery or oestrogen therapy, should stop treatment after three months because of the low risk of recurrence.\textsuperscript{17} \textsuperscript{31} In patients with a first unprovoked pulmonary embolism, who are estimated to have a risk of recurrence of 10\% at one year and 30\% at five years if they stop treatment, the decision whether to extend treatment is sensitive to patients' preferences and their individual risk of bleeding.\textsuperscript{19} There is a lower risk of recurrence in women than in men, and in those who have a normal D-dimer level a month after stopping therapy. Therefore, extended therapy may not be justified in women with a first unprovoked pulmonary embolism who have a negative D-dimer test a month after stopping anticoagulants.\textsuperscript{19} \textsuperscript{34} Thrombophilia testing has little influence on the treatment of venous thromboembolism.\textsuperscript{30} \textsuperscript{35}

**Antiplatelet therapy**

Results from two recent placebo controlled randomised trials support that aspirin reduces risk of recurrent venous thromboembolism by about a third in patients with a first unprovoked venous thromboembolism who have completed at least three months of anticoagulant therapy.\textsuperscript{40} Therefore, if patients are not candidates for extended anticoagulant therapy, this reduction in recurrent venous thromboembolism can be included in the overall assessment of benefit to risk for indefinite aspirin therapy.

**Inferior vena cava filters**

Vena cava filters block emboli from reaching the lungs.\textsuperscript{47} \textsuperscript{55} We limit use of filters to patients with acute proximal deep vein thrombosis or pulmonary embolism who cannot be given anticoagulants. Observational studies, however, suggest that filters may also benefit patients with pulmonary embolism and hypotension who do receive anticoagulants.\textsuperscript{48} \textsuperscript{39} Removable filters can be used in patients with short term contraindications to anticoagulation, but only about 25\% are removed and the long term safety of those that remain is uncertain.\textsuperscript{17}

**Contributors:** Both authors contributed to writing the manuscript and take responsibility for its integrity. CK is guarantor.

### FUTURE RESEARCH QUESTIONS

- Should systemic thrombolytic therapy or other thrombus removal techniques be used to treat pulmonary embolism associated with right ventricular dysfunction?
- Which patients with a first unprovoked pulmonary embolism should receive anticoagulant therapy for three months rather than indefinitely?
- Do all patients with asymptomatic incidental pulmonary embolism require treatment?
- Which patients with CT pulmonary angiography findings suggestive of isolated subsegmental pulmonary embolism should receive anticoagulant therapy?

### TIPS FOR NON-SPECIALISTS

- Anticoagulant therapy should be started before diagnostic testing if there is high clinical suspicion for pulmonary embolism or if testing will be delayed.
- Pulmonary embolism is ruled out without further testing by low clinical suspicion for pulmonary embolism (such as Wells pulmonary embolism score ≤4) and a negative D-dimer test.
- D-dimer testing should not be performed if it is very probable that patients will have a positive result even if pulmonary embolism is not present (such as after major surgery).
- Computed tomography (CT) pulmonary angiography is associated with substantial radiation so it should be used selectively, particularly in younger patients (≥40 years old).
- Anticoagulant therapy is not invariably indicated in patients who have an isolated subsegmental pulmonary embolism on CT pulmonary angiography or an incidental pulmonary embolism on a CT scan that was done for another reason.
- Low molecular weight heparin is often the preferred long term anticoagulant for patients with cancer.

Diagnosis and management of supraventricular tachycardia

Zachary I Whinnett, consultant cardiologist, S M Afzal Sohaib, British Heart Foundation clinical research training fellow and cardiology specialty registrar, D Wyn Davies, consultant cardiologist

The term supraventricular tachycardia (SVT) encompasses many tachycardias in which atrial or atrioventricular nodal tissue are essential for sustaining the arrhythmia (box 1). In practice, however, the term SVT is generally used to refer to atrioventricular nodal re-entry tachycardia (AVNRT), atrioventricular re-entry tachycardia (AVRT), and atrial tachycardia; in this review we follow that convention. We reviewed the literature to provide an up to date summary of our understanding of the mechanism for these arrhythmias, and we describe the approach to their diagnosis and management. Atrial fibrillation has been reviewed recently so is not discussed in detail here. Much of the clinical evidence in this field is derived from observational and registry data, with a limited number of randomised control studies.

What is a supraventricular tachycardia?

SVTs are produced by disorders of impulse formation (causing generation of rapid electrical impulses from a small area) and/or disorders of impulse conduction, which result in re-entrant tachycardias, where tachycardia is produced because the electrical impulse repeatedly travels around a circuit. Re-entrant tachycardias typically require an extrasystole to initiate them. SVTs are among the few medical conditions that can be cured.

What are the different types of SVT?

AVNRT

AVNRT is caused by a re-entrant circuit involving the posterior and anterior inputs into the compact atrioventricular node. A quarter of the population has two pathways that input into the compact atrioventricular node, one of which is a rapidly conducting pathway and the other a slower conducting pathway; these two pathways form the circuit for AVNRT (fig 1).

The extrasystole that triggers the tachycardia is critically timed so that the faster pathway is still refractory from the last sinus beat (that is, it is not yet ready to conduct an impulse because it is still recovering from depolarisation). The electrical impulse therefore propagates exclusively down the slow pathway, which has a shorter refractory period (that is, it takes less time to recover from depolarisation) and then returns up the fast pathway, which has by then recovered. The circuit for typical AVNRT is thus formed.

Less commonly, activation travels anterogradely down the fast pathway and returns up the slow pathway, forming atypical AVNRT. These different mechanisms result in very different appearances on the surface electrocardiogram (ECG). In the typical form, atrial and ventricular activation occur virtually simultaneously (because the impulse returns up the fast pathway at the same time as travelling down the His-Purkinje system), so the P waves are invisible in the QRS complexes (a pseudo-RSR’ pattern in lead V1 often provides a clue to the presence of the P wave), whereas the delayed atrial activation via the slow pathway in atypical AVNRT produces inverted P waves typically in the middle of or late in the RR interval.

Typical AVNRT presents as a short RP tachycardia (the ECG during tachycardia has a RP interval shorter than PR interval) while atypical AVNRT produces a long RP tachycardia (RP interval longer than PR interval) (fig 2). AVRT (including Wolff-Parkinson-White syndrome) AVRT is also a re-entrant tachycardia; it requires the presence of an accessory pathway, a small strand of myocardium that bridges the normal insulation between atria and ventricles (fig 3).

Some pathways can conduct impulses only from the ventricle to the atrium and are known as concealed accessory pathways. Others can conduct in both directions and usually produce pre-excitation of the ventricle because they conduct more rapidly than the atrioventricular node. This early ventricular activation shows on the 12 lead ECG as a delta wave at the start of the QRS (fig 3). The terminal portion of the QRS complex is narrow, reflecting the rapid conduction via the His-Purkinje system once the atrioventricular node has been crossed. The degree of pre-excitation varies depending on the time required to cross the atrioventricular node and the location of the accessory pathway.

The diagnosis of Wolff-Parkinson-White syndrome describes patients with a delta wave on the surface ECG who also experience palpitations.
AVRT is usually triggered by a critically timed atrial extrasystole that finds the accessory pathway refractory, therefore antegrade conduction occurs exclusively down the atrioventricular node. The accessory pathway is no longer refractory by the time the wave front reaches its ventricular insertion and it therefore conducts retrogradely to the atrium—the re-entrant circuit is thus formed (fig 3); this activation pattern is termed orthodromic AVRT, and produces a narrow complex tachycardia. Rarely, antegrade conduction travels down the accessory pathway returning to the atrium via the atrioventricular node, producing antidromic AVRT, which has broad QRS complexes that exaggerate the pattern of pre-excitation seen in sinus rhythm because ventricular activation occurs exclusively via the accessory pathway.

Atrial tachycardia

Atrial tachycardia may result from either abnormal impulse formation or a re-entrant mechanism. Atrial tachycardias are commonly classified according to whether they originate from a small localised area in the atrium (focal atrial tachycardia) or involve a larger re-entrant circuit (macro re-entry).

Focal atrial tachycardia

In focal atrial tachycardia there is generation of rapid electrical impulses from a small localised area in the atria (fig 4).

Multifocal atrial tachycardia

Multifocal atrial tachycardia is less common than focal atrial tachycardia and occurs most often in acutely unwell patients and those with pulmonary disease and/or digoxin toxicity. At least three different morphologies of P wave are usually present.4

Macro re-entrant atrial tachycardia

The re-entrant circuit involves a large area of the atrium. The commonest is “typical” atrial flutter where the re-entrant loop circles the right atrium (fig 5). Other re-entrant atrial tachycardias are seen in patients who have structural heart disease and in those who have had previous surgery (increasingly in those who have had catheter ablation procedures to treat atrial fibrillation).1

Who gets SVT?

People of all ages, either sex, and any ethnicity can develop SVT. In a large retrospective observational study in the United States the peak incidence of SVT presentation was in the middle decades of life (AVNRT at 48 (range 30-66) years; AVRT at 36 (18-64) years; and atrial fibrillation at 50 (31-69) years).4 A higher proportion of AVNRT cases occur in women, and AVRT is more likely to affect men.7 No sex difference was observed for atrial fibrillation. SVTs usually manifest themselves as recurrent palpitations, can seriously impair quality of life,4 and often prompt visits to

**Box 1 Differential diagnosis of a narrow complex tachycardia**

**Common causes**

primary care doctors and acute medical units. The incidence in a large cohort in the United States was found to be 35/100 000 patient years, with a prevalence of 0.2%. An estimated prevalence for atrial fibrillation is 0.4% to 1% in the general population.10

How does SVT present?

Common symptoms include palpitations, chest pain, anxiety, lightheadedness, pounding in the neck, shortness of breath, and uncommonly syncope.11

Sudden onset and offset of palpitations is typical for a re-entrant arrhythmia, while for sinus tachycardia onset and offset is usually gradual. Patients with AVNRT or AVRT may be able to terminate palpitations with vagal manoeuvres such as the Valsalva manoeuvre, breath holding, or coughing.

Some patients can identify triggers such as caffeine or alcohol intake, which can initiate re-entrant tachycardia by increasing the frequency of extrasystoles.

In the absence of an acute episode the examination is usually normal. In a patient with tachycardia, prominent jugular venous A waves caused by atrial contraction against the closed tricuspid valve may be seen.11

What investigations are needed?

Electrocardiography

Attempts should always be made to capture the arrhythmia during an episode of palpitations. We recommend giving the patient a copy to ensure it is never lost and is easily available to health professionals. A rhythm strip should be recorded if 12 lead electrocardiography is not available, and every effort should be made to capture the termination of the tachycardia.

For patients with non-sustained episodes of palpitations, an ambulatory electrocardiograph or an event monitor can be useful in capturing an ECG during an episode.

Narrow complex tachycardia is most frequently seen (QRS <120 ms), but less commonly the QRS complexes are broad during tachycardia. Even though supraventricular tachycardias can present with broad QRS complexes, in the initial evaluation, a broad complex tachycardia should be treated as a ventricular tachycardia until proven otherwise.

A 12 lead ECG in sinus rhythm should also be recorded and carefully examined for the presence of a delta wave. In figure 2 we suggest how to analyse the 12 lead ECG during tachycardia.

Echocardiography

Echocardiography is an important investigation for patients presenting with palpitations. The presence of structural heart disease such as left ventricular impairment should prompt urgent referral and investigation. Left ventricular impairment is associated with an increased risk of sudden cardiac death,13 and patients are less likely to tolerate tachycardia. Such patients should not be prescribed class 1 antiarrhythmic drugs, such as flecainide.14

Most patients with SVT have a structurally normal heart. In a series of 145 patients referred for ablation, only 4% had heart failure.15 However, certain types of structural heart disease are associated with particular SVTs. Patients with Ebstein’s anomaly (congenital displacement of the septal tricuspid valve leaflet into the right ventricle) have an increased frequency of right sided accessory pathways.16 Incisional atrial tachycardia occurs as a result of re-entry around surgical scars and is a major source of morbidity in the growing population of survivors of congenital heart disease.14

What are the acute management options in SVT?

Non-drug treatment

Patients presenting with sustained tachycardia should be assessed for haemodynamic stability; rarely, the arrhythmia is so poorly tolerated that immediate electrical cardioversion is needed. With the important exception of pre-excited atrial fibrillation (in which case the ECG shows an irregular, broad complex tachycardia, with variation of
the QRS morphology (fig 6), the first line manoeuvre is usually to slow conduction through the atrioventricular node. This may either terminate the tachycardia if the mechanism is dependent on the atrioventricular node (AVNRT, AVRT) or provide diagnostic information in the case of atrial tachycardia (P wave morphology exposed and lack of dependence on the atrioventricular node to maintain the tachycardia). A continuous 12 lead ECG recording should be made during these manoeuvres (fig 7).

Atrioventricular node conduction can be slowed by vagal stimulation with carotid sinus massage or the Valsalva manoeuvre.

Pre-excited atrial fibrillation should be managed with electrical cardioversion, or by flecainide infusion if the tachycardia is haemodynamically well tolerated and the heart is normal.

Drug treatment

If vagal manoeuvres are unsuccessful in slowing atrioventricular conduction then, unless the patient is asthmatic, the ACC/AHA/ESC guidelines recommend intravenous adenosine as first line medication. Adenosine is preferred owing to its rapid onset of action and short half life. In a randomised double blinded placebo trial in participants with SVT, tachycardia was terminated in 91% of those who received adenosine (at a dose of either 6 mg or 12 mg) and in 16% of those receiving placebo.\(^1\) When administering adenosine, ensure that resuscitation equipment is available in case the rare complications of bronchospasm or ventricular fibrillation occur.

The effectiveness of intravenous verapamil seems similar to that of adenosine in terminating SVT. In a randomised controlled trial, intravenous verapamil (2.5-7.5 mg) resulted in termination of tachycardia in 91% of patients, compared with termination in 95% of those receiving adenosine (6 mg dose followed by a 12 mg dose if required).\(^2\) A meta-analysis of eight trials with a total of 605 patients, found similarly high rates of termination with both adenosine and verapamil (91% v 90%), with slightly higher rates of minor adverse effects and lower rates of hypotension described with adenosine.\(^3\) \(\beta\) blockers are a further option and are effective in lowering heart rate, but in a small randomised study intravenous esmolol converted only 6% of SVTs to sinus rhythm.\(^4\) Amiodarone\(^5\) and flecainide are further options. Acute administration of flecainide successfully restored sinus rhythm in 72% of patients with AVRT and 83% with AVNRT.\(^6\)

Macro re-entrant atrial tachycardias are not usually responsive to antirhythmic drugs and usually require electrical cardioversion (or overdrive atrial pacing, where tachycardia is terminated by rapid pacing of the atrium using either an existing pacemaker or temporary pacing lead in the right atrium) to restore sinus rhythm. The ACC/AHA/ESC guidelines recommend that before cardioversion the same guidelines for thromboembolic prophylaxis are followed for atrial flutter as for atrial fibrillation (international normalised ratio 2-3, or arrhythmia duration <48 hours, or no evidence of atrial thrombus on transoesophageal echocardiography).\(^7\)

**What are the long term management options?**

In general, improvement of quality of life is the major therapeutic goal for SVTs, and treatment strategies should be guided according to symptoms and patient preference. Patients troubled by recurrent symptomatic episodes should be offered treatment; options include medication or catheter ablation. Patients can be taught the Valsalva manoeuvre and some find this helpful in controlling their symptoms. This can be described to the patient as simulating straining on the toilet, or trying to breathe out forcefully while keeping the mouth closed and nose pinched.

There have been no large scale randomised studies comparing these treatments. However, data from prospective non-randomised studies suggest that catheter ablation results in a greater reduction in symptoms and higher quality of life scores compared with medical treatment.22 25

Patients with pre-excitation (delta wave on ECG) warrant special consideration. Such patients are at risk of sudden cardiac death from ventricular fibrillation induced by rapidly conducted atrial fibrillation. The findings from a recent meta-analysis suggest that in patients who do not have palpitations, this risk seems to be relatively low (1.25 per 1000 person years, 95% confidence interval 0.57 to 2.19 per 1000 person years).26 Symptoms of palpitations appear to be associated with an increased risk of ventricular fibrillation.27

We advise referring patients with pre-excitation to an electrophysiologist for further assessment. Patients with documented broad complex tachycardia (QRS duration >120 ms and heart rate >100 beats/min), even if they have only had a single episode, are also best referred early. Box 2 outlines which patients to refer to an electrophysiologist.

Drug treatment
In general drug treatment is reserved for minimising symptoms while awaiting catheter ablation or for long term management of patients who decline catheter ablation or in whom the procedure carries an unacceptably high risk. Drug treatment may be effective in reducing the frequency of symptoms but complete suppression is uncommon.28

A major limitation in evaluating antiarrhythmic agents for treatment of SVTs is the absence of large, multicentre, randomised, placebo controlled studies.

For AVNRT and AVRT without pre-excitation, agents to block atrioventricular node conduction are commonly used as first line medication, although only limited data are available on the long term efficacy of these medications. Data from a small, randomised, double blind trial, showed that verapamil, propranolol, and digoxin all reduced the frequency of symptoms, with all equally effective.29

For patients who do not respond to these drugs, alternatives include flecainide and sotalol.30 Although only relatively small numbers of patients have been included in randomised studies of flecainide and sotalol, the available data suggest they can be effective in reducing symptoms. In one small placebo controlled study 79% of patients in the flecainide group and 15% in the placebo group did not experience symptoms, though the follow-up period was only eight weeks.31 Proarrhythmia, including ventricular tachycardia, has been reported in 6% of patients.32 Agents to slow atrioventricular node conduction are often co-administered, as flecainide may predispose to atrial flutter with 1:1 atrioventricular conduction.33

Flecainide is not recommended in patients with structural or ischaemic heart disease, in whom it is associated with an increased risk of sudden cardiac death.34 Amiodarone is generally not recommended owing to the potential for serious adverse effects in patients with a benign condition. However, it may be used to treat atrial tachycardias resistant to other treatments, particularly in patients with structural heart disease and in elderly people.

Catheter ablation
Catheter ablation provides a definitive management option for SVT and is usually done under local anaesthesia as a day case. Catheters capable of recording electrical activation in the heart are inserted via the femoral vessels and manipulated under x ray guidance. Radiofrequency energy delivered via a catheter is used to create small localised areas of scar.

In AVNRT, the slow pathway is targeted with the aim of modifying conduction so that re-entrant tachycardia can no longer be sustained. Both acute and long term success rates for this procedure are high. In a large observational study acute success was achieved in 98% of cases.35 A meta-analysis of 10 observational studies comprising 1204 patients reported a 4.3% recurrence rate.36 Serious complications are uncommon, the most serious being atrioventricular block requiring pacemaker therapy (affecting 1% of patients in early series).37 38 39

AVRT is also amenable to catheter ablation. No randomised prospective studies have been conducted, but observational studies and registries have observed acute success rates of more than 95% and recurrence rates less than 5%.39 40 Atrioventricular block is a risk in cases where the accessory pathway is close to the atrioventricular node and the His bundle; the use of cryothermal energy may reduce this risk.41 Other complications are reported to occur in less than 2-3% of patients and include vascular injury, bleeding, venous thrombosis, pulmonary embolism, myocardial perforation, systemic embolism (in the case of a left sided accessory pathway), and rarely, death (0-0.2%).42 43

Focal atrial tachycardia can also be successfully treated with catheter ablation, although randomised control trials are lacking, and evidence is limited to small observational studies. Acute success rates of 85%.44 45 with recurrence rates of 8% have been reported.46

For re-entrant atrial tachycardias, radiofrequency ablation has high success rates and is often used as first line treatment.47 48 Radiofrequency ablation is the treatment of choice for typical atrial flutter. This practice is supported by the findings from a medium sized randomised study which found that, compared with medical treatment, as first line treatment ablation produced higher rates of sinus rhythm (80% v 36%), fewer hospital admissions, and a lower occurrence of atrial fibrillation.49

After the procedure, most patients can return to their normal activities very quickly. We recommend they avoid heavy lifting for two weeks after the procedure. In the UK, the Driver and Vehicle Licensing Agency states that car drivers (group 1 entitlement) may not drive for two days after successful catheter ablation (vocational drivers (group 2) for two weeks afterwards) if the arrhythmia was not or did not have the potential to be incapacitating. If the arrhythmia was or had the potential to be incapacitating, the restriction is six weeks after successful ablation.50

QUESTIONS FOR FUTURE RESEARCH
- Uncertainty remains about the optimal management of patients with asymptomatic pre-excitation (delta wave on the ECG)–in particular, whether sufficiently sensitive risk stratification is possible or whether most patients should be managed with catheter ablation of their accessory pathway
- There is ongoing development of invasive and non-invasive methods for mapping complex arrhythmias, such as atrial tachycardias occurring after ablation for atrial fibrillation. These have the potential to help with diagnosis and to guide the catheter ablation procedure

TIPS FOR NON-SPECIALISTS
- If a patient presents with tachycardia always record an ECG and give the patient a copy; this can be helpful for future management
- Broad complex tachycardia is ventricular tachycardia until proved otherwise
- For narrow complex tachycardia, the first step is usually to slow AV node conduction with either a Valsalva manoeuvre or adenosine. This provides diagnostic information and will usually terminate AVNRT and AVRT
- For patients with recurring symptoms, catheter ablation has high acute and long term success rates

Aortic dissection is caused by an intimal and medial tear in the aorta with propagation of a false lumen within the aortic media. It is part of the “acute aortic syndrome”—an umbrella term for aortic dissection, intramural haematoma, and symptomatic aortic ulcer (table). Acute dissection is the most common aortic emergency, with an annual incidence of 3.4 per 100 000 in the United Kingdom and United States, which exceeds that of ruptured aneurysm. The prognosis is grave, with 20% preadmission mortality and 30% in-hospital mortality.

Who is at risk?

The causes of aortic dissection are multifactorial, and both inherited susceptibility and acquired degenerative disease have been implicated. Several modifiable and non-modifiable risk factors are recognised, the most important of which are discussed below.

Hypertension

Systemic hypertension is one of the most important risk factors for aortic dissection and is present in 40-75% of patients presenting with the condition. Systolic hypertension exacerbates the differential haemodynamic forces acting on the relatively mobile aortic arch and the relatively fixed ascending and descending thoracic aorta. A cohort study of 175 patients identified physical exertion or emotional stress as the direct predecessor of acute pain in 66% of acute dissections, primarily as a result of acute changes in blood pressure during the event.

Race and sex

A cross sectional study of 951 patients by the International Registry of Acute Aortic Dissection, comprising data from 12 international referral centres, showed that 68% of all patients presenting with the condition were male and 79% were white.

Connective tissue diseases

Various connective tissue diseases predispose to the inherent weakening of the aortic wall and subsequent dissection, and these diseases are especially important in patients under 40 years. These include Marfan’s syndrome with fibrillin defects, which is seen in 15-50% of patients under 40 years; Ehlers-Danlos type IV with abnormal synthesis of type III procollagen; and other connective tissue disorders associated with cystic medial necrosis.

Congenital cardiovascular abnormalities

A cross sectional study described a fivefold to 18-fold increased risk of dissection in 516 patients with bicuspid aortic valves. This increased risk was attributed to a co-inherited developmental defect of the proximal aorta, which conferred a predilection towards apoptosis of the cellular components of the aortic media, and subsequent medial weakening and aortic dilation. The presence of a bicuspid aortic valve was also associated with dissection in a greater proportion of patients under 40 years (9% under 40 v 1% over 40; P=0.001). A prospective study of 631 patients from the adult congenital heart disease database showed that the coexistence of coarctation of the aorta with a bicuspid aortic valve significantly increases the risk of acute aortic complications such as dissection.
How do patients present?

Patients typically present with the abrupt onset of sharp tearing or stabbing chest pain, which may improve slightly over time, although pain may be absent in 10% of patients. Asymptomatic presentation is more common in patients with diabetes. The pain may radiate to the neck in type A dissection or to the interscapular area in type B aortic dissection. Acute rupture or inadequate perfusion—depending on the site and extent of the dissection—may cause a patient to become unconscious. Interrupted perfusion may result in neurological deficits, symptomatic limb ischaemia, or visceral ischaemia. A cross sectional study of 617 patients with type A dissection found focal neurological deficits in 17% of patients. One report from the International Registry of Acute Aortic Dissection showed that aortic regurgitation and pulse deficit were present in 32% and 15% of patients, respectively. Hypotension was seen in 25% of patients with type A dissection, whereas hypertension was typical in type B dissection.

Many differential diagnoses exist (box). Specific features, however, may alert clinicians to probable dissection. Consensus guidelines from the American Heart Association describe three categories of high risk features to identify patients at greatest risk: predisposing conditions, pain features, and examination findings. High risk predisposing conditions include Marfan’s syndrome, recent aortic manipulation, or a known thoracic aneurysm. High risk pain features include an abrupt onset of ripping, tearing, or stabbing pain in the chest, back, or abdomen. High risk features of the examination include a pulse or blood pressure discrepancy, neurological deficit, a new murmur of aortic regurgitation, and shock. Urgent aortic imaging is needed in patients who have one or more high risk feature, but who present with no electrocardiographic changes of myocardial infarction and no history or examination findings that strongly suggest an alternative diagnosis. Although the specificity of this approach is unknown, a sensitivity of 95.7% has been reported.

How are patients initially managed?

The emergency management of patients with suspected aortic dissection entails adequate resuscitation and optimisation for subsequent imaging and intervention. This includes ensuring adequate oxygenation and ventilation, with careful monitoring of respiratory function. Two large bore intravenous lines should be established for intravenous fluid resuscitation, with close monitoring of heart rate, heart rhythm, blood pressure, and urine output. β blockers may be given to reduce the rate of blood pressure changes and the shear forces on the aortic wall; aim for a heart rate of 60-80 beats/min and systolic blood pressure of 100-120 mm Hg. However, a careful balance must be maintained between suppressing tachycardia and hypertension and ensuring adequate end organ perfusion (by monitoring urine output; mental and neurological state; and peripheral vascular status, including the development or progression of carotid, brachial, and femoral bruits). Twelve lead electrocardiography is essential to exclude concurrent myocardial ischaemia, which would necessitate urgent discussion with cardiology colleagues about managing acute coronary syndrome in the context of a potential aortic dissection. Undertake definitive imaging and further intervention only once the patient is haemodynamically stable.

How is aortic dissection diagnosed?

Retrograde aortography was the gold standard for assessing patients in the 1970s and 1980s, but it has been superseded by cross sectional imaging, which performs better and has a better safety profile. Although chest radiography and electrocardiography are often ordered in the emergency care setting, these tests cannot establish or exclude the diagnosis of dissecting aortic aneurysm.

D-dimers are raised in aortic dissection and it has been suggested that a concentration below 500 ng/ml, which is already used to rule out pulmonary embolism, can exclude acute dissection (negative likelihood ratio of 0.07) in the first 24 hours. However, these data were derived from a population of patients undergoing imaging for dissection in a tertiary centre. The high pre-test probability of dissection in this group limits the applicability of the study’s findings.

and the safety of using D-dimer testing to screen for dissection in all patients with non-coronary chest pain requires further study. Biomarkers such as smooth muscle myosin heavy chain protein have also proved to be less than useful in diagnosis.¹⁷

Computed tomography can help the clinician rapidly confirm or exclude aortic dissection, classify its extent, and diagnose any complications. Correct categorisation of type A or type B dissection (fig 1) is imperative to plan treatment. Patients commonly need more than one non-invasive imaging test to acquire all necessary information. A cross sectional study of 464 patients reported computed tomography angiography as the initial investigation in 61% of cases, echocardiography in 35%, aortography in 4%, and magnetic resonance angiography in 2%.”¹⁵

Computed tomography angiography
Multidetector computed tomography angiography is recommended by the European Society of Cardiology as the first line of investigation for patients with suspected acute dissection.¹ This investigation can assess factors that are important in the planning of open or endovascular surgery, including the extent of dissection, the relative calibre of true and false lumens, and the involvement of aortic side branches. A meta-analysis of 1139 patients with aortic dissection found that multidetector computed tomography angiography had a sensitivity of 100%, specificity of 98%, and diagnostic odds ratio of 6.5.⁴⁰ Outside the emergency setting, electrocardiogram gated computed tomography can provide dynamic information, although its spatial resolution is inferior to magnetic resonance imaging,⁴¹ which reduces its usefulness in planning complex aortic repairs. The disadvantages of computed tomography angiography include the need to use potentially nephrotoxic contrast media, exposure to ionising radiation, and inability to assess functional aortic insufficiency.

Echocardiography
A small prospective cohort study showed that in patients presenting in shock, transthoracic echocardiography had a 78.3% sensitivity and 83.0% specificity for diagnosing proximal dissection.¹⁵ However, the role of this modality is limited because it cannot accurately visualise the descending aorta in most patients, despite its ability to diagnose aortic incompetence. The combined use of transthoracic echocardiography and computed tomography is useful in the absence of multidetector computed tomography functional imaging.⁴² A meta-analysis of cohort studies (1139 patients) found that transoesophageal echocardiography accurately visualised the entire thoracic aorta (sensitivity 98.0%, specificity 95.0%, diagnostic odds ratio 6.1) and, despite the requirement for oesophageal intubation, can be performed at the bedside.⁴³ Unlike static imaging, transoesophageal echocardiography detects aortic regurgitation or pericardial effusion and can provide intraoperative assessment of operator position within the vessel lumen, although it cannot assess the abdominal aorta.³ The operator dependency of transthoracic and transoesophageal echocardiography limits their accuracy and accessibility.

Magnetic resonance angiography
A meta-analysis of diagnostic studies showed magnetic resonance angiography to have a sensitivity of 98% and specificity of 98%, with diagnostic odds ratio of 6.8, in the diagnosis of dissecting aortic aneurysm.⁴⁴ Gadolinium contrast agents used in magnetic resonance angiography are less nephrotoxic than iodinated substances used for computed tomography angiography and there is no associated ionising radiation.⁴⁵ Disadvantages include its limited use in patients with claustrophobia or metal devices, although it can be used in those with nitinol aortic stent grafts.¹ Long acquisition times and limited availability reduce its usefulness in the emergency setting, for which computed tomography angiography is ideal. Magnetic resonance angiography offers greater potential for long term surveillance of treated dissection and for the assessment of stable patients presenting with chronic dissection.¹

How is aortic dissection managed?
Owing to the paucity of evidence from randomised controlled trials, the management of aortic dissection is mainly guided by data from international registries, large series, and expert consensus.¹ ¹⁶ ¹⁷ The balance between medical and surgical management depends on the anatomical features of the lesion and its physiological sequelae.

Type A dissection
Cross sectional studies from the International Registry of Acute Aortic Dissection have suggested that, if left untreated, proximal (Stanford type A or DeBakey type I or II) dissection carries a one week mortality of 50-91%, owing to complications such as aortic rupture, stroke, visceral ischaemia, cardiac tamponade, and circulatory failure.⁴⁵ Drug treatment alone results in a mortality of nearly 20% by 24 hours and 30% by 48 hours (fig 2).⁴⁶ ⁴⁷ Urgent cardiac surgical consultation is therefore imperative. Surgery involves replacing the affected ascending aorta, with or without the aortic arch, with a prosthetic graft; this procedure has an in-hospital mortality of 15-35%.⁴⁸ ⁴⁹ ⁵⁰ A variety of techniques may be needed. For example, proximal extension of the dissection to the aortic valve or ostia of the coronary arteries may require replacement or resuspension of the aortic valve,¹ or coronary artery bypass.⁵¹ The International Registry of Acute Aortic Dissection reported these techniques in 24% and 15% of type A dissections, respectively.⁵² Together with adjunctive measures such as hypothermic circulatory arrest and perfusion of the head vessels,⁵³ surgery for proximal aortic dissection has three year and five year survival rates of 75% (standard deviation 5%) and 73% (6%), respectively.¹

Acute type B dissection
The development of complicated dissection—defined by the presence of visceral or limb ischaemia, rupture, refractory pain, or uncontrollable hypertension—is the key factor that determines both intervention and outcome for patients with type B dissection.⁵⁴ ⁵⁵ ⁵⁶ ⁵⁷ For uncomplicated acute type B dissection, series have shown that drug treatment alone can result in 78% three year survival after discharge from hospital.⁵⁸ Current guidelines deem this a difficult benchmark to surpass,⁵⁹ and medical management remains the gold standard. Careful regulation of systolic blood pressure at 100-120 mm Hg is needed to minimise haemodynamic shear stress and discourage rupture.⁵⁹ ⁶⁰ ⁶¹ β blockers (such as propranolol and metoprolol) are first line agents. Calcium channel blockers (such as non-dihydropyridine agents) are useful in patients with chronic obstructive pulmonary disease and those who cannot tolerate β blockers.⁶² ⁶³ Endovascular treatment is increasingly possible
with low mortality, and its role in uncomplicated acute type B dissection will be clarified by the results of the Acute Dissection Stent-grafting or Best Medical Treatment (ADSORB) trial (NCT00742274), which will randomise patients to best medical treatment, with and without stent grafting. Until these data are available, uncomplicated type B dissection should be medically managed.

Intervention, usually endovascular repair using a stent graft, is necessary for complicated acute type B dissection. A prospective cohort study of 159 patients reported that, if untreated, this pathology carries a mortality of 50%. Conventional open surgery for complicated dissection has a 30 day mortality of 30%, whereas meta-analysis has shown that endovascular treatment has a 30 day mortality of 9.8%. Long term postoperative surveillance is mandatory: a prospective cohort study of 125 patients suggested that complete thrombosis of the false lumen may be achieved in only 44% of cases, with 20% of dissections rupturing within five years from continual aortic expansion. Multiple cohort studies have shown that even after complete false lumen thrombosis, 16% of patients develop evidence of dissection in the unstented distal aorta, which requires surgical reintervention.

Chronic type B dissection

Uncomplicated chronic type B dissection can be managed conservatively, but many of these patients develop complications, the foremost of which is formation of an aneurysm, which may require surgical intervention. Data on the natural course of the disease suggest that 15% of chronic type B dissections will be complicated by an aneurysm and ongoing research is directed at predicting patients at high risk of this complication, so that they can be targeted for earlier intervention.

Chronic dissection is difficult to treat. Conventional open surgery has an appreciable death rate and poses considerable physiological challenges, including the need for posterolateral thoracotomy, single lung ventilation, cardiopulmonary bypass, hypothermia, heparinisation, cerebrospinal fluid drainage, and circulatory arrest to prevent stroke and paraplegia. The endovascular approach is associated with less morbidity and mortality; a systematic review of 810 patients found that one year survival is higher after endovascular stenting than after open surgery (endovascular surgery 93%; open surgery 79%). However, the long term efficacy of an endovascular approach to preventing long term aortic related death is still unclear.

How should patients be followed up?

Ten year survival rates of patients who are discharged from hospital range from 30% to 60%. The underlying pathophysiology of aortic medial disease and defective wall structure confers an ongoing risk of further dissection, aneurysmal degeneration, and rupture. A prospective cohort study of 721 patients found this risk to be higher in women and that annual mortality was 12% once the aortic diameter exceeded 6 cm. Consequently, the European Society of Cardiology recommends regular cross sectional imaging of the aorta, preferably with magnetic resonance angiography, at one, three, and 12 months after discharge and every six to 12 months thereafter, depending on aortic size. Various experts also advocate the combined use of echocardiography with axial imaging for routine surveillance. All patients should receive lifelong antihypertensive treatment, including β blockers, with a target blood pressure of 120/80 mm Hg.

The sequelae of endovascular and open repair also merit surveillance. A small prospective cohort study reported that reintervention was needed in 27.5% of patients after open repair because of extension or recurrence of dissection, formation of a localised aneurysm remote from the original repair, graft dehiscence, aortic regurgitation, or infection. A systematic review of the mid-term outcomes of endovascular treatment found high rates of reintervention for late morbidities, such as endoleak (8.1%), formation of a distal aneurysm (7.8%), and rupture (3.0%), thereby justifying mandatory postoperative surveillance.
A PATIENT’S PERSPECTIVE

I was relaxing at home one evening when I experienced sudden and extreme chest pain, which was followed by my left leg going numb. I called for an ambulance, which took me to the nearest hospital. After a computed tomography scan, I was diagnosed with a type A aortic dissection and transferred urgently to a regional vascular centre. The surgeons opened my chest and stitched a graft into the top of my aorta. Unfortunately, I had a mild stroke afterwards, which they had warned me about. I am still recovering from this but feel lucky to have survived, considering the high mortality rate.

I stayed well for a year but then developed chest pain and fever. This gradually worsened over four weeks and I was again admitted to my local hospital, where a computed tomography scan showed that I had pneumonia, pleural effusion, and now a type B dissection. They transferred me to the regional vascular centre, where the team decided that because this dissection was chronic and I was otherwise well, I did not need further intervention. I was investigated and treated for a bleeding stomach ulcer. I did well and was then discharged home but was readmitted a week later because I had recurrent chest pain and was coughing blood. A computed tomography scan found no clot in my lungs but showed that the aorta had increased in diameter from 5.9 cm to 7.9 cm. After three days in intensive care, where they controlled my blood pressure, I’m feeling better. I still am an inpatient at the regional vascular unit and am awaiting further surgery on my aorta. The surgeons have said that because of the complexity of my disease, I may be better suited to open rather than keyhole surgery.

UNANSWERED QUESTIONS AND ONGOING RESEARCH

- Which patients with uncomplicated type B dissection might benefit most from intervention? Research currently centres on defining a subgroup at greatest risk of future aneurysmal dilation despite best medical treatment (for example, aortic diameter >40 mm at presentation)22
- The INvestigation of STEnt Grafts in Aortic Dissection (INSTEAD) trial will report the long term outcomes of endovascular stent grafting for uncomplicated chronic type B dissection (conducted across seven European centres)22
- The Acute Dissection Stent-grafting or Best Medical Treatment (ADSORB) trial will report the success of endovascular stent grafting in patients randomised to best medical treatment with and without stent grafting for uncomplicated acute type B dissection
- The mid-term success of stent grafting for dissection will be clarified by publication of the results of postmarket registries (CAPTIVA (NCT01181947) and VIRTUE (NCT01213580))

TIPS FOR NON-SPECIALISTS

- Refer patients with confirmed aortic dissection (or symptomatic high risk patients) to a regional cardiovascular unit for urgent diagnostic investigation and treatment
- Young patients with a history of connective tissue disease (such as Marfan’s disease) or congenital cardiovascular disease (such as bicuspid aortic valves) are at high risk
- Maintain systolic blood pressure at 100-120 mm Hg in patients with a history of dissection; prescribe antihypertensive drugs (including β blockers) and deal with other modifiable cardiovascular risk factors
- Ensure that patients with a history of dissection are enrolled in a surveillance programme at a regional cardiovascular unit

Extracorporeal life support

Alan M Gaffney, specialist registrar in anaesthesia,1 Stephen M Wildhirt, professor of cardiothoracic surgery,2 Michael J Griffin, consultant anaesthetist,3 Gail M Annich, associate professor paediatric critical care medicine,4 Marek W Radomski, professor of pharmacology1

Extracorporeal life support (ECLS) is a variation of cardiopulmonary bypass. Whereas cardiopulmonary bypass facilitates open heart surgery for a number of hours, extracorporeal life support maintains tissue oxygenation for days to weeks in patients with life-threatening respiratory or cardiac failure (or both).

As technology advances, indications increase, and the numbers of specialist centres rise, more doctors are likely to find themselves assessing patients for early referral, discussing this support option with relatives, directly or indirectly managing patients on extracorporeal life support, and providing follow-up outpatient and community-based care. During the recent H1N1 influenza A pandemic, one third of patients admitted to the intensive care unit with severe respiratory failure required extracorporeal life support.1

Evidence from case series, cohort studies, registry database analyses, and randomised controlled trials form the basis of this overview.

What happens during extracorporeal life support?
The circuit consists of tubing taking deoxygenated blood from the patient, a pump, an artificial lung, a heat exchanger, and tubing returning oxygenated blood to the patient (fig 1).

Venous-venous cannulation is used for isolated respiratory failure (tissue hypoxia secondary to hypoperfusion) with or without respiratory failure (table 1).

Venous-venous
A double lumen cannula is commonly placed in a major vein. Deoxygenated blood flows from the venae cavae and oxygenated blood is returned to the right atrium (fig 1). Alternatively, separate inflow and outflow cannulas may be used (fig 2A).

Blood is removed distal to the right atrium and returned directly into the right atrium in an attempt to reduce mixing of deoxygenated with oxygenated blood, and to reduce recirculation of oxygenated blood within the circuit. It is impossible to prevent all mixing and recirculation, and so, in the absence of pulmonary gas exchange, arterial oxyhaemoglobin saturation as low as 80% is common. Adequate oxygen delivery to the tissue, therefore, requires a sufficiently high cardiac output and a haematocrit above 40%.2

Venous-arterial
Cannulas are placed in a major artery and one or more major veins. Venous blood is oxygenated and pumped back directly into the arterial circulation, bypassing both the heart and lungs.

Femoral arterial cannulation is common in adults (fig 2B), whereas the carotid artery is commonly cannulated in infants (fig 2C). In femoral artery cannulation a distal down flow cannula may be needed to prevent leg ischaemia, whereas in carotid cannulation, collateral circulation must be relied on for adequate brain perfusion.

Existing transthoracic cardiopulmonary bypass cannulas may be used where extracorporeal life support is needed immediately after open heart surgery (fig 2D).

In the presence of native heart function, oxygenated blood may not reach the proximal aorta, and this results in cardiac and upper body hypoxaemia (fig 2B). An increase in blood flow rate, a change to venous-venous extracorporeal life support, or placement of an extravenous return cannula may be needed.

Anticoagulation
Because of blood-surface interaction, an infusion of unfractionated heparin is necessary to prevent thrombosis within the circuit and embolism to the patient.

Ventilation
Positive end expiratory pressure is applied to the lungs and the ventilator is set to deliver low tidal volumes, low inspiratory pressures, and a low inspired oxygen fraction. These so called rest settings help to prevent ventilator induced lung injury, oxygen toxicity, and ventilator associated haemodynamic compromise.3 Prevention of further lung injury may be the major advantage of extracorporeal life support.

SUMMARY POINTS

- Extracorporeal life support is a type of cardiopulmonary bypass that supports the lungs, heart, or both for days to weeks in patients in intensive care with reversible life threatening respiratory or cardiac disease.
- Venous-venous cannulation is used for respiratory failure and venous-arterial cannulation for cardiac failure (with or without respiratory failure).
- Bleeding and thrombosis are the most common serious complications.
- Extracorporeal life support is used in children and adults; neonates with respiratory failure have the highest survival rates.
- Timing of extracorporeal life support is important—the specialist centre should be consulted early in the course of illness.
Which patients benefit?
Extracorporeal life support is a support modality rather than a treatment in itself. Its use is restricted to highly specialised centres. It is invasive, complex, resource intensive, and can be associated with serious complications. Extracorporeal life support is, therefore, mostly reserved for patients with a high risk of death who have failed conventional management and where the underlying respiratory or cardiac disease is reversible. It has also been used as a bridge to transplant and placement of a ventricular assist device, to aid weaning from cardiopulmonary bypass, and as an adjunct to cardiopulmonary resuscitation.

The greatest number of cases and highest survival rates have been reported in neonates with respiratory failure (table 2). Most of the evidence supporting extracorporeal life support for other age groups and indications consists of case reports, case series, and analyses of the Extracorporeal Life Support Organization database, although some randomised controlled trials have been reported. Randomised controlled trials are difficult to conduct given the relatively low numbers of patients requiring extracorporeal life support across many centres, the heterogeneity of underlying pathologies, and the speed of technological advances.

Children
The first cases of successful extracorporeal life support management of “moribund infants” were reported in 1974. Thereafter, case series and cohort studies reported improved outcomes, when compared with standard care, in neonates supported with extracorporeal life support for respiratory and cardiac failure. Analysis of cases registered with the Extracorporeal Life Support Organization showed similar improved outcomes.

Four randomised trials met inclusion criteria for a recent Cochrane Collaboration review of extracorporeal life support for severe respiratory failure in newborn infants. Risk of mortality was typically reduced by 44% in infants given extracorporeal life support. The authors concluded that a policy of using extracorporeal life support resulted in “significantly improved survival without increased risk of severe disability.”

Extracorporeal life support undertaken for cardiac failure constitutes less than a quarter of reported cases in children. No prospective randomised controlled trials have assessed effectiveness in this population. However, case series and registry analyses suggest that extracorporeal life support, where available, benefits children with severe life threatening cardiac failure.

Adults
Extracorporeal life support was first used successfully in an adult patient in 1972. In 1979, a randomised prospective multicentre trial of conventional ventilation versus the addition of venous-arterial extracorporeal life support in 90 adults with severe acute respiratory failure reported high mortality (about 90%) in both groups. This is probably a reflection of the deleterious ventilatory strategies used at the time, venous-arterial rather than venous-venous cannulation, and older technologies. Since then, many case series have shown improved success in adults. Recently, a multicentre randomised controlled trial of conventional ventilator support versus extracorporeal life support for severe adult respiratory failure in 180 patients was published (the conventional ventilation or extracorporeal membrane oxygenation (ECMO) for severe adult respiratory failure (CESAR)) trials. Of patients allocated to consideration for extracorporeal life support, 63% survived to six months without disability compared with 47% of those allocated to conventional care. Those randomised to the intervention arm were managed in a single centre where 75% went on to receive extracorporeal life support. Patients in the control arm received conventional ventilation in the referring centres.

Fig 1 Double lumen cannula version of venous-venous extracorporeal life support for respiratory failure: deoxygenated blood from both the superior and inferior venae cavae passes into one lumen of the double lumen cannula. Blood flows in tubing to a pump and on to an oxygenator and heat exchange unit, before being returned to the right atrium through the second lumen with an oxygen-haemoglobin concentration approaching 100%. Here, oxygenated blood mixes with deoxygenated blood that has bypassed the double lumen cannula. This mixture of oxygenated and deoxygenated blood (oxyhaemoglobin saturation of around 80%) is pumped by the heart through the non-functioning lungs into the aorta and on to the organs and tissues of the body. Blue: intravascular deoxygenated blood; red: intravascular oxygenated blood; dark red: intravascular and intracardiac mixed oxygenated and deoxygenated blood; IVC: inferior vena cava; SVC: superior vena cava.
No randomised controlled trials have compared extracorporeal life support with conventional care in adults with cardiac failure. Most evidence supporting adult cardiac extracorporeal life support comes from non-randomised trials, case series, and the Extracorporeal Life Support Organization registry database, as is the case for children.

Cardiopulmonary resuscitation
Extracorporeal life support has been instituted emergently during in-hospital cardiopulmonary resuscitation in children and adults. Case series have reported variable survival rates, and overall survival to hospital discharge rates of 29% in adults, 38% in neonates, and 39% in paediatric patients are reported in the Extracorporeal Life Support Organization registry database (table 2).

Cost effectiveness
Where randomised controlled trials have incorporated economic evaluations into the study design, extracorporeal life support has been demonstrated to be as cost effective as other life extending technologies in common use in intensive care units in developed countries.

What are the main complications?
Bleeding (7-34%) and thrombosis (8-17%) are the most common serious complications. Because of blood-surface interaction, clots can form in the circuit and embolise with potentially devastating consequences. Systemic infusion of unfractionated heparin and the use of heparin bonded circuits help to reduce thrombus formation but bleeding risk is then increased. The delicate balance between haemostasis and thrombosis requires frequent clinical and laboratory monitoring with replacement of coagulation factors, fibrinogen, platelets, and antithrombin III, as necessary. Monitoring and appropriate treatment for disseminated intravascular coagulation (2-5%), haemolysis (7-12%), and fibrinolysis is also needed. Cannulation (7-20%) and surgical site bleeding (6-34%) are common. Invasive procedures and operations should be avoided.

Intracranial bleeding (1-11%), especially in neonates; gastrointestinal haemorrhage (1-4%); and pulmonary haemorrhage (4-8%) may also occur.

All organ systems can be affected by hypoxia and hypoperfusion before and during extracorporeal life support.

**Fig 2** A: an alternative venous-venous extracorporeal life support (ECLS) cannulation; deoxygenated blood is drained from the femoral vein with oxygenated blood being returned to the right atrium. B-D: various venous-arterial configurations. B: blood is drained from the femoral vein and returned to the femoral artery where oxygenated blood flows in a retrograde direction up along the aorta; when some residual cardiac function remains, oxygenated ECLS blood mixes with deoxygenated blood ejected from the left ventricle. C: a cannulated carotid artery, a site often used in infants. D: transthoracic right atrial and aortic cardiopulmonary bypass cannulae. Blue: intravascular and intracardiac deoxygenated blood; red: intravascular oxygenated blood; dark red: intravascular and intracardiac mixed oxygenated and deoxygenated blood.

The brain is particularly vulnerable to damage by each of the above mechanisms and so, in addition to haemorrhage, seizures (2-10%) and infarction (1-8%) are common complications.

Despite these problems, extracorporeal life support is becoming ever safer, especially when appropriately selected patients are managed in specialised units with well trained and experienced staff supported by multidisciplinary teams.

When should patients be referred?
Extracorporeal life support should be considered in patients with severe, life threatening respiratory or cardiac failure that does not respond to conventional intensive care management. The disease process must be reversible or, failing this, the patient should be a candidate for transplantation or ventilricular assist device placement.

Table 3 lists the most common underlying diseases in patients reported to the Extracorporeal Life Support Organization registry. Indications and contraindications vary among centres and continue to change as experience accrues and technology improves. Extracorporeal life support may be relatively contraindicated in patients who: are considered to be too far into the course of their disease; have been on conventional treatment for too long (usually >7-10 days); have pre-existing conditions that affect quality of life or that may be incompatible with normal life if the patient recovers (for example, brain injury, end stage malignancy, risk of systemic bleeding with anticoagulation); or are too young or too small (<42 weeks’ gestational age, <2 kg).

Although there are indices and scoring systems that help clinicians to determine the most appropriate time to consult with referral centres or to start extracorporeal life support (table 4), these serve only as guides and are neither rigidly nor universally applied. Referring hospitals should become familiar with their local specialist centre’s referral guidelines. In all cases, early discussion with the specialist centre is imperative to ensure appropriate patient selection and timely transfer.

What are the long term effects?
Survivors of extracorporeal life support are more likely than the general population to have neurodevelopmental deficits, behavioural problems, and respiratory morbidities. However, when compared with the conventional care arms of randomised controlled trials, no between-group differences are seen for these outcomes. Patients require rehabilitation and multidisciplinary follow-up after discharge from hospital. A high index of suspicion for late manifestations of neurodevelopmental problems must be maintained.

Conclusion
Extracorporeal life support is a life saving intensive care resource when used in appropriately selected patients by well trained personnel in well organised centres. Advances in technology and development of antithrombogenic surfaces will continue to lower the complication rates associated with extracorporeal life support, allowing more patients to benefit from its use.

Ongoing and Future Research
• Research into the modification of extracorporeal life support surfaces is ongoing with the goal of preventing thrombosis in the absence of heparin anticoagulation
• Although the conventional ventilation or ECMO (extracorporeal membrane oxygenation) for severe adult respiratory failure (CESAR) trial showed that management of adults with severe respiratory failure in an extracorporeal life support referral centre is superior to conventional management in referring centres, further trials are needed to confirm increased survival attributable to extracorporeal life support alone
• Trials are needed to define the use of extracorporeal life support in acute myocardial infarction (MI)
• Trials of whole body cooling during extracorporeal life support to prevent neurological disability are ongoing
• Trials are warranted to compare outcomes between extracorporeal life support and high frequency oscillatory ventilation

Refeeding syndrome: what it is, and how to prevent and treat it

Hisham M Mehanna, consultant and honorary associate professor, and director12, Jamil Moledina, senior house officer 3, Jane Travis, Macmillan specialist dietitian4

Refeeding syndrome is a well described but often forgotten condition. No randomised controlled trials of treatment have been published, although there are guidelines that use best available evidence for managing the condition. In 2006 a guideline was published by the National Institute for Health and Clinical Excellence (NICE) in England and Wales. Yet because clinicians are often not aware of the problem, refeeding syndrome still occurs.1

This review aims to raise awareness of refeeding syndrome and discuss prevention and treatment. The available literature mostly comprises weaker (level 3 and 4) evidence, including cohort studies, case series, and consensus expert opinion.2 Our article also draws attention to the NICE guidelines on nutritional support in adults, with particular reference to the new recommendations for best practice in refeeding syndrome.2 These recommendations differ in parts from—and we believe improve on—previous guidelines, such as those of the Parenteral and Enteral Nutrition Group of the British Dietetic Association (box 1).4

What is refeeding syndrome?

Refeeding syndrome can be defined as the potentially fatal shifts in fluids and electrolytes that may occur in malnourished patients receiving artificial refeeding (whether enteral or parenteral).3 These shifts result from hormonal and metabolic changes and may cause serious clinical complications. The hallmark biochemical feature of refeeding syndrome is hypophosphataemia. However, the syndrome is complex and may also feature abnormal sodium and fluid balance; changes in glucose, protein, and fat metabolism; thiamine deficiency; hypokalaemia; and hypomagnesaemia.1 6

How common is refeeding syndrome?
The true incidence of refeeding syndrome is unknown—partly owing to the lack of a universally accepted definition. In a study of 10 197 hospitalised patients the incidence of severe hypophosphataemia was 0.43%, with malnutrition being one of the strongest risk factors.7 Studies report a 100% incidence of hypophosphataemia in patients receiving total parenteral nutrition solutions that do not contain phosphorus. When solutions containing phosphate are used, the incidence can decrease to 18%.8

Several prospective and retrospective cohort studies of hyperalimentation in intensive care units have documented the occurrence of refeeding syndrome.6 9 In a well designed prospective cohort study of a heterogeneous group of patients in intensive care units, 34% of patients experienced hypophosphataemia soon after feeding was started (mean [standard deviation] 1.9 [1.1] days).9 Many case reports have highlighted the potentially fatal nature of the condition.11 However, it is often not recognised or maybe inappropriately treated, especially on general wards.4

How does refeeding syndrome develop?
Prolonged fasting The underlying causative factor of refeeding syndrome is the metabolic and hormonal changes caused by rapid refeeding, whether enteral or parenteral. The net result of metabolic and hormonal changes in early starvation is that the body switches from using carbohydrate to using fat and protein as the main source of energy, and the basal metabolic rate decreases by as much as 20-25%.10

During prolonged fasting, hormonal and metabolic changes are aimed at preventing protein and muscle breakdown. Muscle and other tissues decrease their use of ketone bodies and use fatty acids as the main energy source. This results in an increase in blood levels of ketone bodies, stimulating the brain to switch from glucose to ketone bodies as its main energy source. The liver decreases its rate of gluconeogenesis, thus preserving muscle protein. During the period of prolonged starvation, several intracellular minerals become severely depleted. However, serum concentrations of these minerals (including phosphate) may remain normal. This is because these minerals are mainly in the intracellular compartment, which contracts during starvation. In addition, there is a reduction in renal excretion.

Refeeding During refeeding, glycaemia leads to increased insulin and decreased secretion of glucagon. Insulin stimulates glycogen, fat, and protein synthesis. This process requires minerals such as phosphate and magnesium and cofactors such as thiamine. Insulin stimulates the absorption of potassium into the cells through the sodium-potassium

SUMMARY POINTS

- Refeeding syndrome is a potentially fatal condition, caused by rapid initiation of refeeding after a period of undernutrition
- It is characterised by hypophosphataemia, associated with fluid and electrolyte shifts and metabolic and clinical complications
- Awareness of refeeding syndrome and identification of patients at risk is crucial as the condition is preventable and the metabolic complications are avoidable
- Patients at high risk include chronically undernourished patients and those who have had little or no energy intake for more than 10 days
- Refeeding should be started at a low level of energy replacement. Vitamin supplementation should also be started with refeeding and continued for at least 10 days
- Correction of electrolyte and fluid imbalances before feeding is not necessary; it should be done alongside feeding

SOURCES AND SELECTION CRITERIA

We used the terms “refeeding”, “syndrome”, and “hypophosphataemia” to search the databases Medline, Embase, PubMed, Cochrane, CINAHL, and AMED (Allied and Complementary Medicine Database), as well as cross checking with reference lists, textbooks, and personal reference lists. We assessed the 151 identified papers for relevance. We assessed the quality of evidence in original articles according to guidelines published on the Evidence-Based On-Call website.12
For patients with electrolyte deficits the new guidelines recommend immediate start of nutritional support at a lower rate, rather than waiting until the electrolyte imbalance has been corrected (as was recommended by previous guidelines), thus potentially avoiding further nutritional deterioration in patients.

**What electrolytes and minerals are involved in the pathogenesis?**

**Phosphorus**

Phosphorus is predominantly an intracellular mineral. It is essential for all intracellular processes and for the structural integrity of cell membranes. In addition, many enzymes and second messengers are activated by phosphate binding. Importantly it is also required for energy storage in the form of adenosine triphosphate (ATP). It regulates the affinity of haemoglobin for oxygen and thus regulates oxygen delivery to tissues. It is also important in the renal acid-base buffer system.

In refeeding syndrome, chronic whole body depletion of phosphorus occurs. Also, the insulin surge causes a greatly increased uptake and use of phosphate in the cells. These changes lead to a deficit in intracellular as well as extracellular phosphorus. In this environment, even small decreases in serum phosphorus may lead to widespread dysfunction of cellular processes affecting almost every physiological system (see box A on bmj.com).

**Potassium**

Potassium, the major intracellular cation, is also depleted in undernutrition. Again, serum concentration may remain normal. With the change to anabolism on refeeding, potassium is taken up into cells as they increase in volume and number and as a direct result of insulin secretion. This results in severe hypokalaemia. This causes derangements in the electrochemical membrane potential, resulting in, for example, arrhythmias and cardiac arrest.

**Magnesium**

Magnesium, another predominantly intracellular cation, is an important cofactor in most enzyme systems, including oxidative phosphorylation and ATP production. It is also necessary for the structural integrity of DNA, RNA, and ribosomes. In addition, it affects membrane potential, and deficiency can lead to cardiac dysfunction and neuromuscular complications.

**Glucose**

Glucose intake after a period of starvation suppresses gluconeogenesis through the release of insulin. Excessive administration may therefore lead to hyperglycaemia and its sequelae of osmotic diuresis, dehydration, metabolic acidosis, and ketoadosis. Excess glucose also leads to lipogenesis (again as a result of insulin stimulation), which may cause fatty liver, increased carbon dioxide production, hypercapnoea, and respiratory failure.

**Vitamin deficiency**

Although all vitamin deficiencies may occur at variable rates with inadequate intake, thiamine is of most importance in complications of refeeding. Thiamine is an essential coenzyme in carbohydrate metabolism. Its deficiency result in Wernicke’s encephalopathy (ocular abnormalities, ataxia, confusional state, hypothermia, coma) or Korsakoff’s syndrome (retrograde and anterograde amnesia, confabulation).

**Sodium, nitrogen, and fluid**

Changes in carbohydrate metabolism have a profound effect on sodium and water balance. The introduction of carbohydrate to a diet leads to a rapid decrease in renal excretion of sodium and water. If fluid repletion is then instituted to maintain a normal urine output, patients may rapidly develop fluid overload. This can lead to congestive cardiac failure, pulmonary oedema, and cardiac arrhythmia.

**How can refeeding syndrome be prevented?**

Identification of high risk patients is crucial (boxes 2 and 3).

Any patient with negligible food intake for more than five days is at risk of developing refeeding problems. Patients may be malnourished as a result of reduced intake (for example, owing to dysphagia, anorexia nervosa, depression, alcoholism); reduced absorption of nutrition (as in, for example, inflammatory bowel disease, coeliac disease); or increased metabolic demands (for example, in cancer, surgery). High risk patients include those who have been chronically undernourished, especially those who also have diminished physiological reserve. Patients with dysphagia (for example, as a result of stroke) in particular may be at high risk.

**BOX 2 PATIENTS AT HIGH RISK OF REFEEDING SYNDROME**

- Patients with anorexia nervosa
- Patients with chronic alcoholism
- Oncology patients
- Postoperative patients
- Elderly patients (comorbidities, decreased physiological reserve)
- Patients with uncontrolled diabetes mellitus (electrolyte depletion, diuresis)
- Patients with chronic malnutrition:
  - Marasmus
  - -Prolonged fasting or low energy diet
  - -Morbid obesity with profound weight loss
  - -High stress patient unfed for >7 days
- Malabsorptive syndrome (such as inflammatory bowel disease, chronic pancreatitis, cystic fibrosis, short bowel syndrome)
- Long term users of antacids (magnesium and aluminium salts bind phosphate)
- Long term users of diuretics (loss of electrolytes)

---

**BOX 1 WHY USE THE NICE GUIDELINES ON REFEEDING SYNDROME?**

- The guidelines are the most recent comprehensive review of the literature on refeeding syndrome
- The guideline development group was strongly multidisciplinary with wide ranging consultation with both professional and patient stakeholders
- The guidelines clearly identified points of good practice and areas for further research
- The new guidelines give explicit clinical criteria for patients “at risk” and “highly at risk” of developing refeeding syndrome, enabling better identification and prevention
- For patients with electrolyte deficits the new guidelines recommend immediate start of nutritional support at a lower rate, rather than waiting till the electrolyte imbalance has been corrected (as was recommended by previous guidelines), thus potentially avoiding further nutritional deterioration in patients
The figure summarises how to prevent and treat refeeding syndrome. To ensure adequate prevention, the NICE guidelines recommend a thorough nutritional assessment before refeeding is started. Recent weight change over time, nutrition, alcohol intake, and social and psychological problems should all be ascertained. Plasma electrolytes (especially phosphate, sodium, potassium, and magnesium) and glucose should be measured at baseline before feeding and any deficiencies corrected during feeding with close monitoring.

The NICE guidelines recommend that refeeding is started at no more than 50% of energy requirements in “patients who have eaten little or nothing for more than 5 days.” The rate can then be increased if no refeeding problems are detected on clinical and biochemical monitoring (level D recommendation—see box 3).

For patients at high risk of developing refeeding syndrome, nutritional repletion of energy should be started slowly (maximum 0.042 MJ/kg/24 hours) and should be tailored to each patient. It can then be increased to meet or exceed full needs over four to seven days. In patients who are very malnourished (body mass index ≤14 or a negligible intake for two weeks or more), the NICE guidelines recommend that refeeding should start at a maximum of 0.021 MJ/kg/24 hours, with cardiac monitoring owing to the risk of cardiac arrhythmias (level D recommendation). This explicit specification of the rate of refeeding in severely malnourished patients should help avoid complications arising from rapid refeeding and is an improvement on previous guidelines.

The NICE guidelines also state that correcting electrolyte and fluid imbalances before feeding is not necessary and that this should be done along with feeding. This is a change from previous guidelines and potentially avoids prolongation of malnourishment and its effects on patients.

All guidelines recommend that vitamin supplementation should be started immediately, before and for the first 10 days of refeeding. Circulatory volume should also be restored. Oral, enteral, or intravenous supplements of the potassium, phosphate, calcium, and magnesium should be given unless blood levels are high before refeeding. Good quality studies on the exact levels of supplementation are lacking, however, and so the required levels of these supplements cited by NICE (figure) are only level D recommendations.

Electrolyte levels should be measured once daily for one week, and at least three times in the following week. Urinary electrolytes could also be checked to help assess body losses and to guide replacement.

### Guidelines for management. Adapted from the guidelines of NICE and the British Association of Parenteral and Enteral Nutrition

**How can refeeding syndrome be detected and treated?**

Refeeding syndrome is detected by considering the possibility of its existence and by using the simple biochemical investigations described above. If the syndrome is detected, the rate of feeding should be slowed down and essential electrolytes should be replenished. The hospital specialist dietetics team should be involved.

The best method for electrolyte repletion has not yet been determined. Hypophosphataemia, hypomagnesaemia, and hypokalaemia in hospitalised patients are ideally treated with intravenous supplementation (table), but this is not without risks. A prospective comparative cohort study of 27 patients with severe hypophosphataemia showed the safety of administering 15-30 mmol phosphate over three hours via a central venous catheter in an intensive care unit. However, the researchers reported the need for repeated doses in most patients. Terlevich et al reported efficacy of 50 mmol phosphate infused into a peripheral vein over 24 hours in 30 patients with no pre-existing renal dysfunction on general wards. Further infusions may be required and so careful monitoring of blood levels is required. Caution is needed in patients with existing renal impairment, hypokalaemia (which may worsen), or hypercalcaemia (which may result in metastatic calcification).

Fluid repletion should be carefully controlled to avoid fluid overload as described earlier. Sodium administration should be limited to the replacement of losses. In patients at high risk of cardiac decompensation, central venous pressure and cardiac rhythm monitoring should be considered.

### Conclusion

Adherence to the NICE guidelines for preventing and treating refeeding syndrome (boxes 2 and 3) should reduce the incidence and associated complications of the syndrome. Further research is needed to determine the true incidence of refeeding syndrome and to ascertain the best management protocols.

**BOX 3 CRITERIA FROM THE GUIDELINES OF THE NATIONAL INSTITUTE FOR HEALTH AND CLINICAL EXCELLENCE FOR IDENTIFYING PATIENTS AT HIGH RISK OF REFEEDING PROBLEMS (LEVEL D RECOMMENDATIONS*)**

Either the patient has one or more of the following:

- Body mass index (kg/m²) <16
- Unintentional weight loss >15% in the past three to six months
- Little or no nutritional intake for >10 days
- Low levels of potassium, phosphate, or magnesium before feeding

Or the patient has two or more of the following:

- Body mass index <18.5
- Unintentional weight loss >10% in the past three to six months
- Little or no nutritional intake for 15 days
- History of alcohol misuse or drugs, including insulin, chemotherapy, antacids, or diuretics

*Recommendations derived from low grade evidence–mainly cohort and case series studies–and from consensus expert opinion

**AREAS FOR FUTURE RESEARCH**

- Formulation of consensus definitions and outcomes for reporting studies on nutrition
- Large multicentre studies concentrating on homogeneous, well defined study samples
- High quality trials to identify the best replacement and treatment regimens for phosphate and other minerals for refeeding syndrome

The role of interventional radiology in trauma

Ian A Zealley, consultant radiologist, Sam Chakraverty, consultant radiologist

Most preventable deaths from trauma are caused by unrecognised and therefore untreated haemorrhage, particularly in the abdomen. Haemorrhage causes early deaths, and the associated hypovolaemic shock leads to secondary brain injury and contributes to late death from multiorgan failure. Early management is focused on resuscitation and the diagnosis and treatment of life threatening bleeding to prevent the lethal metabolic disturbance triad of acidosis, hypothermia, and coagulopathy.

Many aspects of immediate trauma care suffer from a lack of high quality prospective research. This review is based predominantly on evidence from retrospective cohort series and is subject to the limitations inherent in this type of level 2 research. There are no prospective randomised controlled trials of interventional radiology in major trauma. Although the volume of level 2 evidence is substantial and contains few contradictory findings, no robust level 1 evidence yet exists. This review aims to summarise the evidence supporting the use of interventional radiological techniques in the management of haemorrhage caused by blunt abdominal trauma.

What is the role of interventional radiology in abdominal trauma?

Interventional radiology uses minimally invasive endovascular techniques to stem haemorrhage. Endovascular haemostatic techniques are established in non-trauma clinical scenarios. In trauma, the main application is to control endovascular haemorrhage by blocking bleeding vessels (transcatheter arterial embolisation (fig 1) or relining them (stent grafting) (fig 2). The objective is to stop the bleeding without the physiological stress of surgery.

Transcatheter arterial embolisation is now an accepted adjunct to non-operative and surgical management protocols in trauma. This parallels its increasing use in other settings of life threatening haemorrhage, such as gastrointestinal and postpartum haemorrhage. Insertion of a stent graft is a well established technique in the management of traumatic rupture of the thoracic aorta.

What injuries are sustained in blunt abdominal trauma?

The frequency of injury to different structures varies among studies. A recent prospective series in which 224 patients with sustained blunt abdominal trauma had computed tomography regardless of their haemodynamic status provides an illustration of patterns of injury (table).

How does interventional radiology compare with surgery for control of haemorrhage after abdominal trauma?

The key question is: what evidence indicates the clinical scenarios in which interventional radiology for stopping haemorrhage is as good as or better than surgery in terms of morbidity and mortality? The evidence base is relatively poor. For transparency, we usually state the type of study and sample size—for example: (a) the evidence that saving a damaged spleen by using embolisation to avoid splenectomy is weak as it is based only on a study of 17 subjects, and (b) single centres reporting their own outcomes may choose to present them in a positive light.

Spleen

Splenectomy used to be the standard treatment for a damaged spleen. However, asplenic patients have impaired short and long term immunity. Unplanned splenectomy for iatrogenic surgical injury carries a twofold to 10-fold increase in the incidence of postoperative infection and double the risk of mortality. A retrospective review of 196 patients with trauma injury found that splenectomy carried a 50% increased risk of postoperative infections.

Several studies suggest that in haemodynamically stable patients embolisation achieves the same survival and reduces the need for splenectomy. A series of 154 patients found that the survival rate of 85% with embolisation was closely similar to the 82% survival in historical controls who had had splenectomy. A Norwegian centre reported outcomes for 133 patients with splenic injuries before and after the introduction of embolisation to the trauma service. The change in practice reduced the laparotomy rate from 55% to 30% and increased the rate of spleen salvage from 57% to 70%. The overall survival rate was stable at 85-89%; the survival rate in the United Kingdom for comparable patients is 78%.

Importantly, embolisation does not obliterate the spleen. A prospective study of 17 patients found that half the splenic bulk was preserved and that serological measures of immune function were normal. Embolisation may preserve splenic function, avoiding the short and long term risks of splenectomy.
Complications in a retrospective series of 140 patients included recurrent haemorrhage in 11%, symptomatic infarct leading to splenectomy in 2%, and abscess in 4%.\(^3\) Two smaller series with a total of 36 patients describe similar outcomes and also report fever in 56% and left pleural effusion in 31%—a form of mild post-embolisation syndrome similar to that seen after tumour embolisation and attributed to tissue infarction.

Liver
For haemodynamically unstable patients with liver injuries the standard approach is rapid “damage control” surgery with extensive packing of liver injuries.\(^16\) Bleeding from central hepatic or portal veins also requires surgical repair, even in haemodynamically stable patients.\(^17\) In this setting embolisation is a potentially attractive adjunctive therapy for patients with ongoing haemorrhage. In one retrospective series seven patients with liver injuries had angiography after damage control surgery; six of these had ongoing bleeding, and embolisation was successful in all seven patients, with no late rebleeds.\(^18\)

The potential impact of interventional radiology is shown in a review of outcomes for 114 patients with liver injuries before and after the introduction of embolisation to a trauma service in Norway.\(^19\) In haemodynamically unstable patients, angiography and embolisation were performed immediately after damage control surgery. In haemodynamically stable patients with high grade injuries, angiography was performed immediately if there was clinical or computed tomography evidence of ongoing bleeding. The change in practice reduced the laparotomy rate from 58% to 34% and lowered the complication rate by 40% (including abscess, biloma, and bile leak). The survival rate was stable at 89-90%; the survival rate in the UK for comparable patients is 78%.\(^1\)

High grade liver injuries cause extensive vascular and biliary disruption that may be exacerbated by treatment. Focal necrosis of devitalised liver tissue is seen after embolisation, especially with extensive injuries; subsequent abscess formation may require percutaneous drainage or surgical intervention.\(^20\)\(^21\) A retrospective study of 71 patients receiving embolisation for hepatic trauma found that complications occurred in 61% (major hepatic necrosis in 42%, abscess in 17%, gallbladder necrosis in 7%, and bile leak in 20%).\(^20\) Surprisingly, mortality in patients with major hepatic necrosis was lower than in those without (7% v 20%, P for difference=0.1).

Kidney
Injuries involving the renal arteries usually occur in conjunction with other solid organ injuries, and require intervention.\(^22\) Embolisation is performed as selectively as possible to maximise preservation of viable, perfused renal tissue. Surgical treatment of similar injuries will often involve nephrectomy.

Recent reports indicate that embolisation is an effective haemostatic technique for these injuries. Initial haemostasis was achieved in all 43 patients reported in three retrospective series.\(^22\)\(^23\)\(^24\) Rebleeding occurred in three patients (two of whom were treated with further embolisation), and abscess occurred in one patient. Ultimately, delayed nephrectomy was performed in five of the 43 patients but there were no deaths.\(^22\)\(^23\)\(^24\)

Pelvic fracture
Bleeding from pelvic fractures may originate from bone, muscle, and large vessels. This adversely influences the prognosis for the severely injured patient (mortality can exceed 25%).\(^25\)\(^26\) so prompt effective management is essential. Pelvic fractures are often associated with other abdominal injuries, emphasising...
the importance of computed tomography in planning effective treatment.

Surgical exploration and control of pelvic bleeding is technically challenging and may disrupt the useful tamponade effect of existing haematoma (fig 3). Endovascular treatment for bleeding pelvic fracture has become an established and reliable technique. In one retrospective study, angiography identified pelvic arterial bleeding in 19 of 26 haemodynamically unstable patients; it also identified that fitting surgical external fixator devices led to avoidable delays to angiography and haemostasis. Pelvic fractures may instead be temporarily immobilised with sheet-wrap techniques to facilitate prompt assessment with computed tomography and subsequent angiography.

Complications of embolisation may be difficult to distinguish from the consequences of the injury itself. A retrospective series of 31 patients reported gluteal necrosis in three patients, all of whom had sustained degloving injuries of the buttock, although the embolisation may have contributed. Another retrospective series—of 100 patients with pelvic fracture of whom 67 received embolisation—found a similar incidence of early complications (skin necrosis, perineal infection, nerve injury) in patients with and without embolisation. Long term complications such as claudication, skin ulceration, and regional pain were also similar across treatment groups, although regional paraesthesia was more common after embolisation.

Might interventional radiology be beneficial for the most severely injured patients?

Although interventional radiology for pelvic bleeding in haemodynamically unstable patients is gaining acceptance, the standard approach to other organ injuries in these patients remains surgery, without prior computed tomography.

The most widely adopted guidelines for management of haemodynamically unstable patients with blunt abdominal trauma advocate laparotomy without computed tomography or attempted endovascular management. Similarly, 97% of trauma surgeons in the United States consider haemodynamic instability to be an indication for immediate splenectomy in blunt splenic injury. The concept that haemodynamically unstable patients should not have computed tomography but should instead proceed direct to laparotomy is widely accepted but not based on any evidence.

However, this philosophy of care is challenged by the speed and clinical utility of modern multidetector computed tomography scanners. Laparotomy allows review and repair of injuries to solid organs and hollow viscera, but assessment of some commonly injured areas such as the retroperitoneum and pelvis is limited. Some patients have bleeding in these regions identified on computed tomography only after surgery has failed, resulting in delayed diagnosis and delayed effective treatment.

Some centres now incorporate multidetector computed tomography into their trauma algorithms even for unstable patients. One prospective study examined outcomes in 252 haemodynamically stable and unstable patients with blunt abdominal trauma who all had immediate computed tomography, with management decisions taken jointly by a senior surgeon and interventional radiologist. Twenty-eight of the 34 haemodynamically unstable patients had active bleeding sites identified, and 13 had embolisation alone for liver, renal, splenic, and/or pelvic injuries. All survived without surgery. Six patients had no active bleeding identified on computed tomography and were successfully managed non-operatively. The survival rate was 31/34 (89%), with laparotomy performed in 15/34 and embolisation in 13/34. The three deaths occurred in patients initially treated surgically. Thus surgery was avoided in over half of these severely injured patients, all of whom would have had immediate laparotomy in most centres. If further prospective studies replicate these findings open surgery might be avoidable in some of the most severely injured patients. Early computed tomography was essential to the success of the management strategy described in this study.
Another study evaluated 19 patients with multiple injuries who exhibited a transient haemodynamic response to initial fluid resuscitation. These patients all had embolisation rather than surgery. Although the average systolic blood pressure at the time of embolisation was 80 (range 65-90) mm Hg, only one patient died from haemorrhage related to their abdominal injuries. A notable feature of this study was that the average time from admission to the start of angiography was only 92 minutes, during which the clinical evaluation, assessment of response to fluid, and computed tomography were performed. By contrast, a 2007 National Confidential Enquiry into Patient Outcome and Death (NCEPOD) that reviewed trauma services in England and Wales found that the average time from admission to computed tomography was 2.3-3.0 hours.

These two small studies suggest that indications for interventional radiology might be expanded to include some haemodynamically unstable patients who would have surgery according to current management algorithms.

What are the barriers to progress in interventional radiology in the United Kingdom?

Despite numerous technological advances in traumatology, surgery, anaesthesia, and radiology the mortality from major trauma has not changed over the past 30 years and is particularly poor in the United Kingdom. Incorporation of interventional radiological techniques into the management of severe injury is intuitively desirable as the additional trauma of surgery is avoided. The use of interventional radiology may increase the number of patients who are successfully managed non-operatively or act as a bridge to definitive surgery in initially unstable patients.

The main barrier to progress is the absence of good evidence. Use of interventional radiology to treat ruptured berry aneurysms is well proved because prospective study designs have several hours’ leeway in which to make treatment decisions after the initial subarachnoid haemorrhage. In major trauma, treatment decisions have to be made immediately so study designs must allow this. Further, in contrast to subarachnoid or myocardial infarction, major trauma is not a discrete diagnosis with straightforward diagnostic criteria. Past research studies into thrombolysis for acute management of myocardial infarction were reasonably easy to organise because the treatment was simple to deliver and could be done by relatively junior medical staff at all times of the day and night. But the numerous possible injury combinations in major trauma require the collaboration of experienced staff from several disciplines (traumatology, anaesthesia, surgery, orthopaedics, radiology) to deliver high quality care. Securing agreement among all members of these teams at several institutions for good recruitment into prospective randomised trials poses a substantial challenge that has not yet been overcome. In addition, serious problems exist regarding consent for research in hyperacute clinical scenarios where patients are usually attending without next of kin. Only after all these challenges have been overcome will it be possible to develop reliable triage tools to decide on early surgery, early endovascular treatment, or conservative management for individual patients.

In the United Kingdom administrative and cultural obstacles are also present. A review of trauma services in the 2007 NCEPOD report described very poor availability of senior clinicians and poor access to immediate computed tomography and interventional radiology. Review of the records of 795 trauma patients found that surgery had been performed in 110 cases but embolisation in only one; perhaps limited awareness accompanies limited availability. The report recommended substantial changes to the organisation of trauma care in the UK and consideration of centralisation of relevant skills and resources to optimise patient care in the future. If these recommendations are met this reorganisation would facilitate future high quality UK research into many of the management areas of major trauma, including clarifying the role of interventional radiology alongside fluid resuscitation and surgery.

Figure 4 illustrates the management pathway used at our institution for treating haemodynamically unstable patients who have blunt abdominal trauma. At any time the senior surgeon involved can divert the patient direct to the operating theatre. The target time from admission to computed tomography is one hour. Resuscitation continues during transfers and scanning; radiology rooms have piped gases and anaesthetic trolleys.

![Fig 3 Axial computed tomogram through the abdomen of a haemodynamically unstable patient after surgical exploration had failed to identify a source of bleeding. Laparotomy released the abdominal tamponade on a retroperitoneal haematoma (dashed arrow), prompting further haemorrhage from the injured right kidney. Extravasation of intravenous contrast (white material, solid arrow) indicates rapid active bleeding. Expansion of the haematoma during surgery prevented reinsertion of the bowel (short arrows) into the abdomen. The liver (Li), normal left kidney (Ki), and constricted “shock” aorta (hollow arrow) are also labelled. The bleeding vessels were successfully treated with embolisation, but the patient died of multiorgan failure caused by the preceding prolonged hypovolaemic shock.](image)

![Fig 4 Management pathway used at authors’ institution for treating haemodynamically unstable patients who have blunt abdominal trauma. Pathway shows decision making on key events, with each responsible specialty (senior level) indicated on the left](image)
The authors acknowledge the substantial contribution made by the peer reviewers, Professor Jon Mos (Glasgow) and David Kessel (Leeds), to the development of this manuscript.

PATHWAYS AND PROTOCOLS FOR MANAGING MAJOR TRAUMA

- All centres should develop robust communication pathways that ensure that management decisions in major trauma cases are as far as possible taken by experienced specialists in trauma surgery, anaesthetics, and diagnostic and interventional radiology
- Clinicians practising in non-specialist centres should identify the most appropriate specialist centre in their vicinity to discuss management protocols for major trauma, including blunt abdominal trauma. Subjects for discussion should include developing pathways of admission that bypass non-specialist centres where possible, and criteria and mechanisms for transferring patients whose outcome is likely to be improved by transfer
- Clinical management protocols and pathways should be developed in the knowledge that most major trauma in the United Kingdom presents outside normal working hours

ADDITIONAL EDUCATIONAL RESOURCES

AREAS FOR FUTURE RESEARCH

- Development and execution of study designs that prospectively randomise trauma patients to treatment arms (rather than retrospective series)
- Evaluation of the impact of immediate computed tomography for all patients with blunt abdominal trauma followed by non-operative management, interventional radiology, or damage control surgery, compared with traditional management algorithms
- For patients with blunt abdominal trauma who are in hypovolaemic shock, determination of the potential for interventional radiology to replace surgery by randomising patients either to (a) traditional immediate surgery or to (b) immediate computed tomography followed by embolisation with or without subsequent surgery, or surgery with or without subsequent embolisation
More titles in
The BMJ Clinical Review Series
This volume deals with a series of important issues in general surgery including:

- The modern management of incisional hernias
- Splenic trauma
- Anal fistula
- Faecal incontinence in adults.

Issues in oncology covered includes:

- Ductal carcinoma of the breast
- Diagnosis and management of anal intraepithelial neoplasia
- Anal cancer
- Oesophageal cancer
- The diagnosis and management of gastric cancer.

Among other conditions discussed are:

- Acute pancreatitis
- Ulcerative colitis
- Crohn’s disease
- Gallstones
- Bariatric surgery for obesity
- Metabolic conditions in adults.
This volume covers a range topics in the management and treatment of cancer. Subjects dealt with include:

- The changing epidemiology of lung cancer with a focus on screening using low dose computed tomography
- Identifying brain tumours in children and young adults
- Prostate cancer
- Screening and the management of clinically localized disease
- The management of women at high risk of breast cancer
- Head and neck cancer with reference to epidemiology, presentation, prevention, treatment and prognostic factors
- Malignant and premalignant lesions of the penis
- Melanoma and advances in radiotherapy.
The book brings together a series of useful articles on a varied range of conditions and lifestyle related issues which are frequently presented in General Practice.

These include:
- Supporting smoking cessation
- The assessment and management of alcohol use disorders
- Diagnosis and management of premenstrual disorders
- Managing patients with multimorbidity in primary care.

Specific conditions discussed include:
- Dyspepsia
- Gout
- Irritable bowel syndrome
- The assessment and management of insomnia in primary care
- The management of ingrowing toenails and fungal nail infections.
This book draws together a collection of current review articles published in the BMJ on clinically important Paediatric topics. Among the many subjects covered in this volume dealing with issues relating to the clinical care of children are contributions on:

- Managing common breastfeeding problems in the community
- The diagnosis of autism in childhood
- Issues relating to obesity in children including epidemiology, measurement, risk factors, screening, its prevention and management
- Identifying brain tumours in children and young adults
- Management of infantile colic
- The use and misuse of drugs and alcohol in adolescence
- Managing common symptoms of cerebral palsy in children
- The developmental assessment of children
- Allergic rhinitis in children
- Diagnosis and management of juvenile idiopathic arthritis
The book brings together a series of useful articles on aspects of orthopaedics, vascular surgery and ENT. Among the many topics discussed are:

- Diagnosis and management of bone stress injuries of the lower limb in athletes
- Treatment and management of tennis elbow
- Achilles tendon disorders
- Management of osteoarthritis of the knee
- The management of abdominal aortic aneurysms
- Venous ulcer disease
- Salivary gland swellings
- Meniere’s disease
- Management of chronic rhinosinusitis
- Investigating the thyroid nodule.
This volume presents a range of articles discussing significant issues in contemporary cardiology and respiratory medicine.

Among the topics covered are:
- Pre-participation screening for cardiovascular abnormalities in young competitive athletes
- The investigation and management of congestive heart failure
- Inherited cardiomyopathies
- Resistant hypertension
- The diagnosis and management of pulmonary hypertension
- Difficult to treat asthmatic conditions in adults
- Sarcoidosis
- How asbestos exposure affects the lungs.
This collection of articles focuses on areas of general medicine which are presented to clinicians at all levels in the profession.

Some of the subjects discussed include:
- Vitamin B12 deficiency
- Viral meningitis
- Acute altitude illnesses
- Assessment and management of alcohol use disorders
- Paracetamol poisoning
- Non-cardiovascular effects associated with statins
- Guillain-Barre syndrome.
- Some of the other medical issues discussed include:
  - Managing health problems in people with intellectual disabilities
  - Adults with Down’s syndrome
  - Issues relating to sickle cell disease.
Are you a healthcare professional or student who wishes to acquire and develop your leadership and management skills? Do you recognise the role and influence of strong leadership and management in modern healthcare?

Clinical leadership is something in which all healthcare professionals can participate in, in terms of driving forward high quality care for their patients. In this up-to-date guide, the authors take you through the latest leadership and management thinking, and how this links in with the Clinical Leadership Competency Framework. As well as influencing undergraduate curricula this framework forms the basis of the leadership component of the curricula for all healthcare specialties, so a practical knowledge of it is essential for all healthcare professionals in training.

Using case studies and practical exercises to provide a strong work-based emphasis, this practical guide will enable you to build on your existing experiences to develop your leadership and management skills, and to develop strategies and approaches to improving care for your patients.

This book addresses:

- Why strong leadership and management are crucial to delivering high quality care;
- The theory and evidence behind the Clinical Leadership Competency Framework;
- The practical aspects of leadership learning in a wide range of clinical environments
- How clinical professionals and trainers can best facilitate leadership learning for their trainees and students within the clinical work-place.

Whether you are a student just starting out on your career, or an established healthcare professional wishing to develop yourself as a clinical leader, this practical, easy-to-use guide will give you the techniques and knowledge you require to excel.
We can all remember a teacher that inspired us, encouraged us and helped us to excel. But what is it that makes a good teacher and are these skills that can be learned and improved?

As doctors and healthcare professionals we are all expected to teach, to a greater or lesser degree, and this carries a great deal of responsibility. We are helping to develop the next generation and it is essential to pass on the knowledge that we have gained during our experience to date.

This book aims to cover the fundamentals of medical education. It has been designed to be a guide for the budding teacher with practical advice, hints, tips and essential points of reflection designed to encourage the reader to think about what they are doing at each step.

By taking the time to read through this book and completing the exercises contained within it you should:

- Understand the needs of the learner
- Understand the skills required to be an effective teacher
- Understanding the various different teaching scenarios, from lectures to problem based teaching, and how to use them effectively
- Understand the importance and sources of feedback
- Be aware of assessment techniques, appraisal and revalidation

This book aims to provide you with a foundation in medical education upon which you can build the skills and attributes to become a competent and skilled teacher.
Would you like to know how to improve your communication skills? Are you looking for a clearly written book which explores all aspects of effective medical communication?

There is an urgent need to improve doctors’ communication skills. Research has shown that poor communication can contribute to patient dissatisfaction, lack of compliance and increased medico-legal problems. Improved communication skills will impact positively on all of these areas.

The last fifteen years have seen unprecedented changes in medicine and the role of doctors. Effective communication skills are vital to these new roles. But communication is not just related to personality. Skills can be learned which can make your communication more effective, and help you to improve your relationships with patients, their families and fellow doctors.

This book shows how to learn those skills and outlines why we all need to communicate more effectively. Healthcare is increasingly a partnership. Change is happening at all levels, from government directives to patient expectations. Communication is a bridge between the wisdom of the past and the vision of the future.

Readers of this book can also gain free access to an online module which upon successful completion can download a certificate for their portfolio of learning/Revalidation/CPD records.

This easy-to-read guide will help medical students and doctors at all stages of their careers improve their communication within a hospital environment.
Are you a doctor or medical student who wishes to acquire and develop your leadership and management skills? Do you recognise the role and influence of strong leadership and management in modern medicine?

Clinical leadership is something in which all doctors should have an important role in terms of driving forward high quality care for their patients. In this up-to-date guide Peter Spurgeon and Robert Klaber take you through the latest leadership and management thinking, and how this links in with the Medical Leadership Competency Framework. As well as influencing undergraduate curricula and some of the concepts underpinning revalidation, this framework forms the basis of the leadership component of the curricula for all medical specialities, so a practical knowledge of it is essential for all doctors in training.

Using case studies and practical exercises to provide a strong work-based emphasis, this practical guide will enable you to build on your existing experiences to develop your leadership and management skills, and to develop strategies and approaches to improving care for your patients.

This book addresses:

- Why strong leadership and management are crucial to delivering high quality care
- The theory and evidence behind the Medical Leadership Competency Framework
- The practical aspects of leadership learning in a wide range of clinical environments (e.g. handover, EM, ward etc)
- How Consultants and trainers can best facilitate leadership learning for their trainees and students within the clinical workplace

Whether you are a medical student just starting out on your career, or an established doctor wishing to develop yourself as a clinical leader, this practical, easy-to-use guide will give you the techniques and knowledge you require to excel.
Are you confused about medical ethics and law? Are you looking for a definitive book that will explain clearly medical ethics and law?

This book offers a unique guide to medical ethics and law for applicants to medical school, current medical students at all stages of their training, those attending postgraduate ethics courses and clinicians involved in teaching. It will also prove a useful guide for any healthcare professional with an interest in medical ethics and law. This book provides comprehensive coverage of the core curriculum (as recently revised) and clear demonstration of how to pass examinations, both written and practical. The title also considers the ethical dilemmas that students can encounter during their training.

This easy to use guide sets out to provide:

• Comprehensive coverage of the recently revised core curriculum
• Consideration of the realities of medical student experiences and dilemmas with reference to recently published and new GMC guidance for medical students
• Practical guidance on applying ethics in the clinical years, how to approach all types of examinations and improve confidence regarding the moral aspects of medicine
• A single, portable volume that covers all stages of the medical student experience

In addition to the core curriculum, this book uniquely explains the special privileges and responsibilities of being a healthcare professional and explores how professional behaviour guidance from the General Medical Council applies to students and medical professionals. The book is a single, accessible volume that will be invaluable to all those who want to thrive, not merely survive, studying and applying medical ethics day to day, whatever their stage of training.
Do you find it difficult to achieve a work-life balance? Would you like to know how you can become more effective with the time you have?

With the introduction of the European Working Time Directive, which will severely limit the hours in the working week, it is more important than ever that doctors improve their personal effectiveness and time management skills. This interactive book will enable you to focus on what activities are needlessly taking up your time and what steps you can take to manage your time better.

By taking the time to read through, complete the exercises and follow the advice contained within this book you will begin to:

- Understand where your time is being needlessly wasted
- Discover how to be more assertive and learn how to say ‘No’
- Set yourself priorities and stick to them
- Learn how to complete tasks more efficiently
- Plan better so you can spend more time doing the things you enjoy

In recent years, with the introduction of the NHS Plan and Lord Darzi’s commitment to improve the quality of healthcare provision, there is a need for doctors to become more effective within their working environment. This book will offer you the chance to regain some clarity on how you actually spend your time and give you the impetus to ensure you achieve the tasks and goals which are important to you.
Unsure of what clinical competencies you must gain to successfully complete the Foundation Programme? Unclear on how to ensure your ePortfolio is complete to enable your progression to ST training?

This up-to-date clinical handbook is aimed at current foundation doctors and clinical medical students and provides a comprehensive companion to help you in the day-to-day management of patients on the ward. Together with this it is the first handbook to also outline clearly how to gain the core clinical competencies required for successful completion of the Foundation Programme. Written by doctors for doctors this comprehensive handbook explains how to successfully manage all of the common cases you will face during the Foundation Programme and:

- Introduces the Foundation Programme and what is expected of a new doctor especially with the introduction of Modernising Medical Careers
- Illustrates clearly the best way to manage, step-by-step, over 150 commonly encountered clinical diseases, including NICE guidelines to ensure a gold standard of clinical care is achieved.
- Describes how to successfully gain the core clinical competencies within Medicine and Surgery including an extensive list of differentials and conditions explained
- Explores the various radiology images you will encounter and how to interpret them
- Tells you how to succeed in the assessment methods used including DOP’s, Mini-CEX’s and CBD’s
- Has step by step diagrammatic guide to doing common clinical procedures competently and safely.
- Outlines how to ensure your ePortfolio is maintained properly to ensure successful completion of the Foundation Programme.
- Provides tips and advice on how to start preparing now to ensure you are fully prepared and have the competitive edge for your CMT/ST application.

The introduction of the e-Portfolio as part of the Foundation Programme has paved the way for foundation doctors to take charge of their own learning and portfolio. Through following the expert guidance laid down in this handbook you will give yourself the best possible chance of progressing successfully through to CMT/ST training.
Not sure what to do when faced with a crying baby and demanding parent on the ward? Would you like a definitive guide on how to manage commonly encountered paediatric cases?

This clear and concise clinical handbook has been written to help healthcare professionals approach the initial assessment and management of paediatric cases commonly encountered by Junior Doctors, GPs, GP Specialty Trainee’s and allied healthcare professionals. The children who make paediatrics so fun, can also make it more than a little daunting for even the most confident person. This insightful guide has been written based on the author’s extensive experience within both a General Practice and hospital setting.

Intended as a practical guide to common paediatric problems it will increase confidence and satisfaction in managing these conditions. Each chapter provides a clear structure for investigating potential paediatric illnesses including clinical and non-clinical advice covering: background, how to assess, pitfalls to avoid, FAQs and what to tell parents. This helpful guide provides:

- A problem/symptom based approach to common paediatric conditions
- An essential guide for any doctor assessing children on the front line
- Provides easy-to-follow and step-by-step guidance on how to approach different paediatric conditions
- Useful both as a textbook and a quick reference guide when needed on the ward

This engaging and easy to use guide will provide you with the knowledge, skills and confidence required to effectively diagnose and manage commonly encountered paediatric cases both within a primary and secondary care setting.
